THE DIAGNOSIS AND TREATMENT OF MAJOR INFECTIONS OF THE HAND*

SUMNER L. KOCH, M.D.
Chicago

IN discussing the subject of infections of the hand it is scarcely necessary for me to remind this association of our indebtedness to Dr. Allen B. Kanavel. Our accurate knowledge of the diagnostic symptoms and of the proper method of treatment of infections of the hand is based upon the original experimental and clinical studies which he began to report in 1905.

There are three types of infections of the hand of so great importance and of such frequent occurrence that every medical man should possess the ability to recognize them promptly and treat them correctly. They are acute lymphangitis, infections of the flexor tendon sheaths, and infections of the fascial spaces of the palm.

Acute Lymphangitis.—An acute spreading infection of the lymphatics usually follows a trivial injury—a penetrating wound from a sliver, a pin, a surgical needle or tonsil snare, a scratch from a nail, or from a sharp splinter of wood or metal. Within a few hours of the injury the affected finger is hot and painful, and there is a more or less diffuse inflammatory reaction about the site of injury. Soon red streaks appear which extend up the forearm (Fig. 1). The patient feels restless and ill; his temperature rises; he has chilly sensations, and within twenty-four hours he may be acutely ill with repeated chills, high fever and prostration.

On examining the hand one finds the greatest reaction about the site of injury, but there is no evidence of pus formation; the symptoms are not confined to the distal phalanx, as in the case of a paronychia or felon; movement of the affected finger does not cause noticeable pain and does not exaggerate the symptoms present. Palpation of the elbow and axilla usually reveals tender and enlarged lymph glands even within twenty-four hours of the onset.

With such a clinical picture—a history of injury, local signs of inflammation, red streaks of lymphatic extension along the forearm and arm, and the early development of systemic symptoms of acute infection—there can be no doubt as to the presence of a virulent and rapidly spreading infection, usually of streptococcic origin. Nor is there any question as to the wisest method of treatment. The patient should be put to bed, the entire upper extremity enveloped in a warm, wet, sterile dressing and fluids given in the largest quantity possible. Surgical intervention in such cases causes a rapid extension of the infectious process with disastrous results. Unless one can secure localization of the infectious process by conservative measures he may be sure that active surgical intervention will only hasten an inevitably fatal outcome.

A typical instance of such an infection came to my attention recently. A physician, forty-eight years of age, sustained a slight abrasion of his right index finger. He paid no particular attention to it, and a few days later, on a Saturday afternoon, operated upon a patient with a Bartholinian abscess. The same evening he noticed that the finger was inflamed and painful. He felt restless and irritable, and finally went to his office and picked at the finger with a scalpel. All Saturday night the finger and hand throbbed and ached; he was restless and slept very little. Early Sunday morning he called a colleague, who infiltrated the finger thoroughly with procaine, incised it, and stated he was certain there was no pus there, for he cut down to the bone.

---

*From the department of surgery, Northwestern University Medical School. Read at the annual meeting of the Southern Minnesota Medical Association, Faribault, Minnesota, August 24, 1931.

30243

When I saw the patient Monday evening he was obviously very ill. Perspiration was standing in beads on his face and neck; his temperature was 103°; he had had several severe chills.

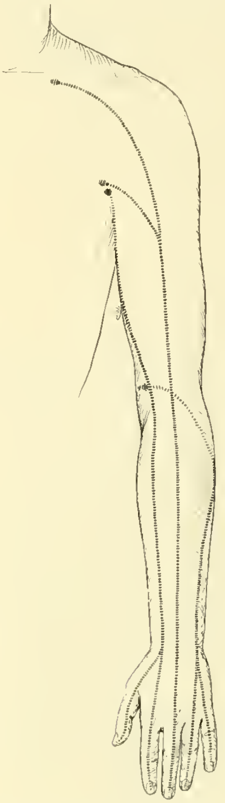

Fig. 1. Position of the main lymphatic trunks, and of the red lines of lymphatic extension in acute lymphangitis. (Kanavel and Mason, Sajous' Encyclopedia of Medicine.)

There was a thin serous discharge from an incision three-quarters of an inch in length on the palmar surface of the right index finger. Red streaks extended up the forearm and arm, converging toward the axilla. Fortunately no further surgery had been done and at the suggestion of a former student of Dr. Kanavel, who had seen the patient Monday morning, a massive, warm, wet dressing had been applied to the entire upper extremity throughout Monday. This treatment was continued; fluids were administered by mouth and by rectum, and the patient made a gradual and uneventful recovery without definite localization of the infection or abscess formation.

The outcome in the majority of cases is not so fortunate a one. Too often the patient's resistance is insufficient to overcome the virulent infection; surgical interference causes wider diffusion of the infection; septicemia and pyemia rapidly develop, and the patient dies.

Tendon Sheath Infections.—Tendon sheath infections usually result from direct inoculation or from extension of infection from the subcutaneous tissues. Their gravity lies in the fact that they spread with remarkable rapidity, and that destruction of the tendon sheath and of the tendon itself ensues in a very short time unless the infected area is drained, and prompt measures instituted to maintain the function of the tendons.

The tendon sheaths of the index, middle and ring fingers extend from a point just distal to the distal flexion crease of the finger to a line closely approximating the distal flexion crease of the palm (Fig. 2). They lie in close apposition to the palmar surface of the phalanges and are separated from the bone only by a thin layer of connective tissue. An infection of the flexor sheaths of any of these fingers makes itself evident very promptly by pain, swelling, inability to extend the fingers completely and by tenderness which corresponds definitely and accurately to the anatomical outlines of the tendon sheath.

The sheath of the long flexor of the thumb begins at a point slightly distal to the distal flexion crease of the thumb, and accompanies the flexor pollicis longus through the palm to terminate a thumb's breadth above the anterior annular ligament in an expansion known as the radial bursa (Fig. 2). Over the first metacarpal bone it lies between the flexor pollicis brevis and the adductor obliquus. The motor branch to the muscles of the thenar eminence lies superficial to the tendon sheath, approximately an inch above the annular ligament. The bursa ends in a blind pouch under the tendon and upon the pronator quadratus, separated by the latter from the wrist joint and the radio-ulnar joint.

The tendon sheath of the flexors of the little finger begins just distal to the distal flexion crease of the fifth finger and extends proximalward to become continuous, in the majority of cases, with the ulnar bursa, a good sized sac which lies over the metacarpal bone of the ring finger and the base of the middle metacarpal bone, and extends proximalward under the anterior annular ligament a thumb's breadth above the ligament (Fig. 2). Here it lies underneath the flexor tendons, upon the pronator quadratus muscle, and is separated by this muscle from the wrist joint. In the region of the wrist joint the ulnar bursa forms a more or less complete sheath for the flexor tendons, being pushed radialward, as it were, in three pockets—one superficial to the tendons, one between the superficial and deep tendons and one, the largest and most easily distensible, underneath the deep tendons.

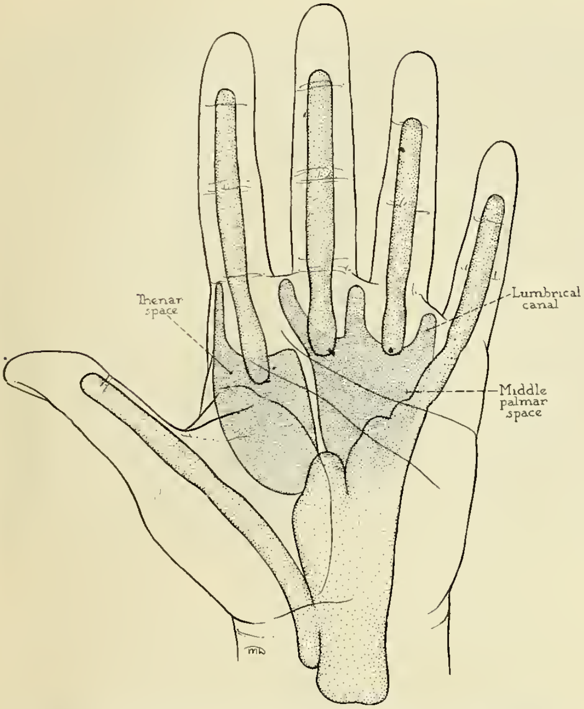

Fig. 2. Diagram showing the tendon sheaths and fascial spaces of the palm. (Kanavel and Mason, Sajous' Encyclopedia of Medicine.)

The exact arrangement of the tendon sheaths in the proximal portion of the palm and over the wrist is subject to considerable variation. The important fact from a practical standpoint is that in the majority of cases the radial and ulnar bursæ communicate with one another by way of an intermediary sheath, so that an infection of the tendon sheath of the thumb and radial bursa usually extends to the ulnar bursa and distally along the tendon sheath of the little finger. An infection arising in the tendon sheath of the fifth finger involves the same structures in the reverse order. From these various sites infection may extend to a number of different places, as will be indicated later.

The diagnosis of a tendon sheath infection is based on symptoms which early in the course of the infection are limited to the area involved, but which tend very quickly to become more difficult of interpretation because of extension of the infection to surrounding tissues. These symptoms are pain, tenderness and other signs of inflammation, frequently out of proportion to the extent of the infected area. The patient holds the affected finger in a slightly flexed position. Any attempt to extend it causes him to wince with pain. By gentle pressure an area of tenderness may be outlined which corresponds accurately to the anatomical outline of the tendon sheath. In every case the dorsum of the affected finger is swollen and edematous because of the direction of lymphatic drainage and the greater distensibility of the tissues of the dorsum of the hand as contrasted with those of the palmar surface.

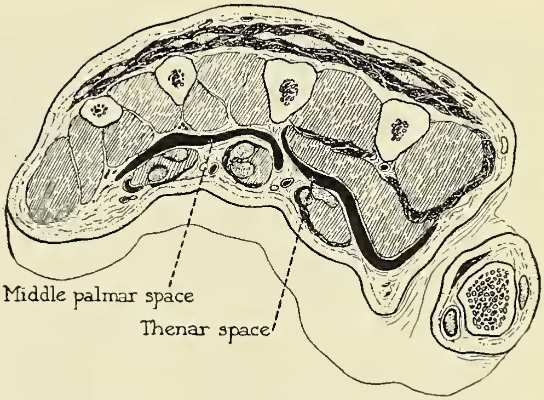

Fig. 3. Cross section of the palm above the metacarpophalangeal joints showing the position of the thenar and middle palmar spaces. (After Kanavel.)

If the infection involves only the index, middle or ring finger there is no doubt as to its location and the freedom of other fingers from infection. With infection of the radial and ulnar bursæ the inflamed swollen wrist, with the tense anterior annular ligament drawn like a taut cord across its volar surface, suggests at once the extension of the infection into the forearm. Since in more than eighty per cent of cases the radial bursa communicates with the ulnar bursa above the wrist it is common to find involvement of both bursæ. In early cases, however, it may be difficult to determine whether one is dealing with one of the less common types in which the bursæ do not communicate with one another. If, for example, the infection has begun in the thumb and spread into the radial bursa one wishes to be certain whether the ulnar bursa and the tendon sheath of the fifth finger are involved. In such a case the position in which the fifth finger is held, the presence of pain on attempted extension of the finger, and the presence of a point of maximum tenderness where the distal flexion crease of the palm crosses the flexor tendons of the fifth finger (Kanavel's sign) are important considerations. If one is still in doubt it is wise through a bloodless field to make an exploratory incision in the palm over the sheath of the flexor tendons of the fifth finger. If no infection is present no harm will be done by such a procedure, but irreparable injury may be done if the infected sheath is not drained. If the primary infection involves the tendon sheath of the fifth finger, the same considerations apply with reference to the radial bursa and the flexor tendon sheath of the thumb.

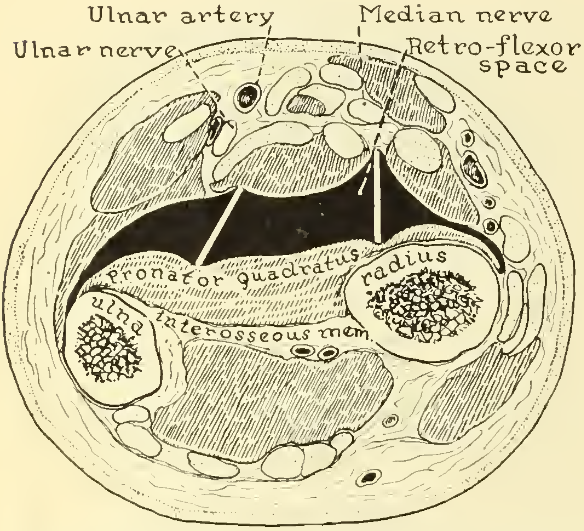

Fig. 4. The retroflexor space above the wrist into which pus ruptures from the radial and ulnar bursæ. (After Kanavel.)

In cases which have been neglected for four or five days, or which have been drained inadequately, the median and ulnar nerves may be so compressed by the pressure of the exudate above the wrist as to be partially anesthetized. In such cases the characteristic symptoms mentioned above—particularly the excruciating pain caused by attempted extension of the affected fingers—are masked, but the history, the location of the primary lesion, the bulging swelling above the wrist, and the general symptoms of severe infection make the diagnosis clear.

When rupture takes place from the tendon sheaths of the index, middle or ring fingers the pus spreads into one of the fascial spaces of the palm, and forms an abscess of the thenar space or the middle palmar space (Figs. 2, 3). (These will be discussed under infections of the fascial spaces.) When rupture takes place from the radial or ulnar bursa the pus at first lies in the retroflexor space between the flexor tendons and the pronator quadratus (Fig. 4). As it spreads upward it dissects between the superficial and deep flexor muscles and tends to become superficial along the ulnar side of the upper third of the forearm. In such an event the entire hand and forearm are dusky red, swollen, tense, and edematous. Vesicles or blebs may cover large areas of the affected extremity. Because of the extent of the involvement and the retention of a large amount of pus under pressure, toxic absorption proceeds at a rapid rate and the general symptoms of severe infection—high fever, rapid pulse, profuse perspiration, prostration, and not uncommonly delirium—indicate the extreme gravity of the condition.

Infection of the Fascial Spaces of the Palm.—These include the thenar space, the middle palmar space and the lumbrical canals which extend distalward from the thenar and middle palmar spaces along the lumbrical muscles. Infection of the fascial spaces of the palm may occur by direct inoculation and as the result of deep, penetrating wounds, but most commonly occurs as the result of extension of a tendon sheath infection.

The thenar space (Figs. 2, 3) lies upon the adductor muscles of the thumb partially covered by the short muscles of the thenar eminence, by the flexor tendons of the index finger and by the accompanying digital vessels and nerves (Figs. 2, 3). It extends ulnarward to the middle metacarpal bone. The middle palmar space lies deep in the palm upon the interosseous muscles, underneath the flexor tendons of the middle and ring fingers. On the radial side it extends to the middle metacarpal bone. On the ulnar side it is partially covered by the overlying distal end of the ulnar bursa.

Tendon sheath infections arising in the index finger tend to rupture into the thenar space. Tendon sheath infections arising in the middle and ring fingers usually rupture into the middle palmar space. In neglected cases tendon sheath infections starting in the thumb may rupture into the thenar space, and tendon sheath infections arising in the fifth finger into the middle palmar space. With pus under great tension rupture from one space into the other may take place.

The symptoms of thenar space infection are pain, tenderness and swelling of the thenar eminence. Normally the thenar eminence is the most prominent portion of the palm, but with infection in the thenar space it stands out in such a pronounced fashion as to elevate the thenar eminence still more above the remainder of the palm and force the thumb away from the hand (Fig. 5). The dorsum of the web between the thumb and index finger is swollen and edematous. Eventually there is extension of the infection along the lumbrical canal on the radial side of the index finger, with tenderness and swelling on the dorsum of the hand between the index and middle fingers.

With infection of the middle palmar space the striking symptoms are the loss of the normal concavity of the palm and the edema and swelling of the dorsum of the hand. Because the pus lies under the flexor tendons and the firm palmar fascia the palmar swelling is not pronounced, but it is sufficient to change the normal concavity of the palm into a slight convexity. Because of the direction of lymphatic drainage the dorsum of the hand is swollen and edematous, but pus will not be found on the dorsum except in those neglected cases in which the infection has extended distalward along the lumbrical canals and passed to the dorsum in the subcutaneous tissue about the web of the fingers. Only in grave, neglected infections in which osteomyelitis has taken place does pus find its way through the barrier of deep fascia, interosseous muscles, and metacarpal bones from the palm to the dorsum of the hand.

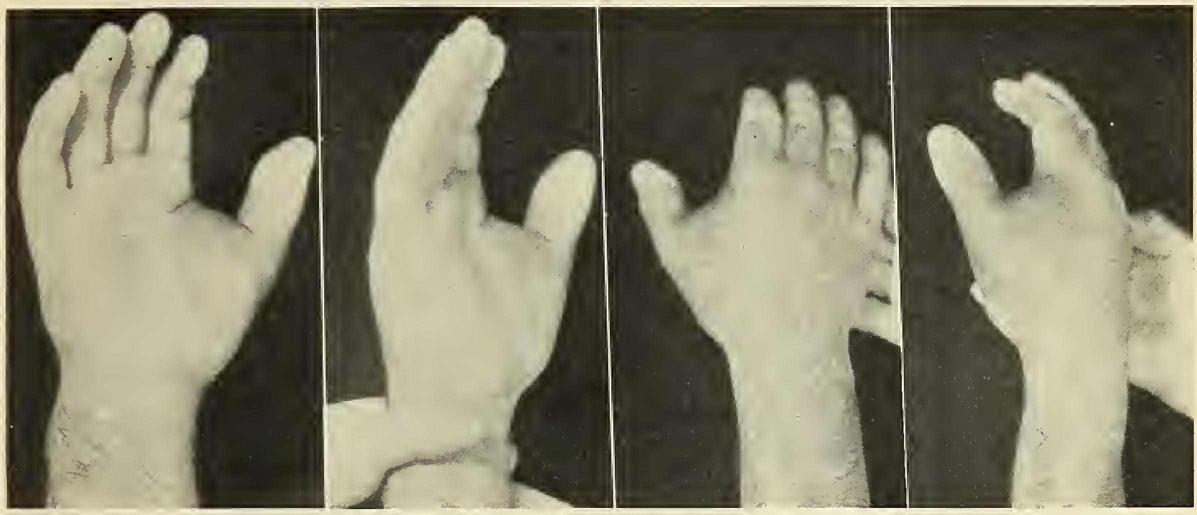

Fig. 5. Infection of thenar space, resulting in marked swelling of the thenar area and forced abduction of the thumb from the index finger.

Treatment of Tendon Sheath and Fascial Space Infections.—The treatment of infections of the tendon sheaths and fascial spaces is to secure adequate drainage as soon as the condition is recognized. This should be done under a general anesthetic such as nitrous oxide, ethylene or ether, and through a bloodless field secured with the aid of a constrictor.

In draining the tendon sheaths of the fingers the incision should be made well to the side of the finger (Fig. 6), so as to avoid the digital nerves and blood vessels, the flexion creases on the palmar surface, and so as to prevent herniation of the tendon from its sheath, a complication that occurs very promptly if the sheath is opened through the middle of the palmar surface of the finger.

On incising a finger with infection of the tendon sheath one is always surprised by the extensive swelling of the subcutaneous tissues, and by the manner in which they seem to fill the entire wound and obstruct the deeper structures from view. Unless this edematous tissue is well retracted it is impossible to secure a clear view of or even to expose the deeply lying tendon sheath. If one can expose the sheath for a little distance before incising it with the scalpel he will find instead of a thin translucent membrane through which the shining tendon may be discerned, a grayish edematous structure which resembles the edematous peritoneum overlying an appendiceal abscess. The moment it is opened the pus pours out. In very early cases the pus may not yet fill the sheath, and may appear only when the tendon is raised from the posterior surface of its sheath.

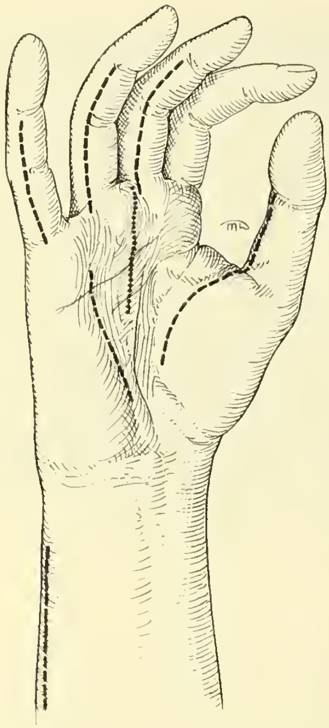

Fig. 6. Incisions for drainage of the middle palmar space and of the tendon sheaths of the fingers and thumb. (Kanavel and Mason, Sajous' Encyclopedia of Medicine.)

If the flexor sheaths of the thumb and little finger are involved the incisions must be extended upward (Fig. 6). One should avoid cutting through the muscles of the thenar eminence in the case of the thumb by making a curved incision to the ulnar side of the thenar eminence and retracting the thenar muscles radialward, and should remember that the flexor tendons of the little finger run obliquely upward and radialward and not in the line of the fifth metacarpal bone. Such an infection also requires an incision on the ulnar side of the forearm to drain the upper, most distensible portions of the ulnar and radial bursæ (Figs. 4, 6). It should always be made at the side, never over the middle of the volar surface, for the pus lies underneath the flexor tendons. A median incision in such a case inevitably leads to extensive fibrosis and destruction of tendons and frequently to operative or postoperative injury of the median nerve.

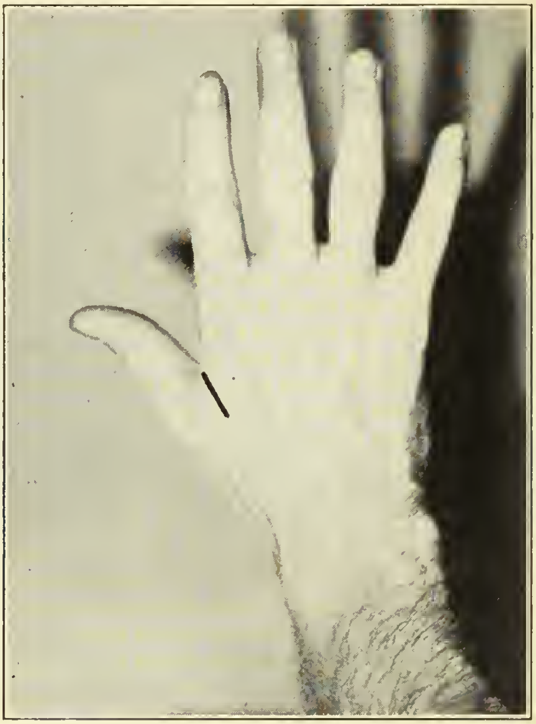

Fig. 7. Line of incision for drainage of thenar space.

The middle palmar space is drained through an incision between the middle and ring fingers, extending from just above the web of the fingers to the middle flexion crease of the palm. The flexor tendons, digital nerves, and blood vessels of the middle finger are retracted to the radial side and the corresponding structures of the ring finger to the ulnar side. The middle palmar space, as it lies behind the flexor tendons, is then widely exposed. Occasionally an additional incision over the lumbrical canal of the ring finger helps to make drainage more complete and hasten recovery. Through the incision indicated for drainage of the thenar space (Fig. 7) a pair of forceps or Kocher dissector is passed upward and ulnarward directly into the abscess cavity as it lies upon the adductor muscles of the thumb.

If drainage incisions are located correctly and of adequate length, an incision on one side of the affected fingers and on the ulnar side of the forearm, in the case of ulnar and radial bursæ infections, suffices for drainage. The use of through-and-through drainage above or underneath a flexor tendon should be carefully avoided. It is the surest possible method of causing necrosis of the tendons.

With infections of the middle palmar and thenar spaces, drains should never be inserted through and through from the palm to the dorsum of the hand. The spaces in question are separated from the dorsal surface by a number of anatomical layers (Fig. 3). Plunging a pair of forceps through the deep volar fascia, the interosseous muscles, between metacarpal bones and through the dorsal aponeurotic and subcutaneous layers in order to drain an accumulation of pus in one of the fascial spaces of the palm renders almost certain the development of osteomyelitis and the formation of persistent sinuses.

After Treatment of Tendon Sheath and Fascial Space Infections.—In order to stop venous oozing after operations and to keep wound edges widely separated, drainage wounds are packed lightly with gauze impregnated with petrolatum. Occasionally rubber tissue is used instead. Tubes are never used because pressure necrosis of tendons and tendon sheaths and extensive fibrosis involving tendon and nerves inevitably result from their use.

In dressing the hand a large sterile towel is laid on the arm board, covered with abdominal pads and sterile dressings, and the outstretched arm is laid on the bed of dressings. More dressings are added to cover the arm; the dressings are saturated with a warm, sterile boric or salt solution and the edges of the towel brought together to enclose the whole. The warm solution is added at two-hour intervals without changing the dressing and a powerful electric light is suspended above the arm to help maintain the heat.

At the end of twenty-four hours the dressings are removed and a sterile dressing reapplied with the same care that was used in applying the original dressing. If one can avoid adding secondary infection, particularly to streptococcic infections of the tendon sheaths, the tendons may be saved and a complete restoration of function secured in a considerable proportion of cases.

The petrolatum gauze is removed at the first or second post-operative dressing. No drainage material is reinserted after removal of the original drains.

As soon as the acute symptoms have subsided, usually at the end of three or four days, an arm bath, used for fifteen or twenty minutes twice daily, is substituted for the continuous moist dressing. After being soaked in a warm, sterile solution the arm is laid on a sterile towel, allowed to dry for a half hour under an electric light and covered with a dry dressing. While the hand is in the bath the patient is urged to move his fingers gently to prevent the formation of fibrous adhesions. Simply moving the fingers through their complete range of motion once or twice daily during the period of forced immobilization suffices to prevent the formation of crippling adhesions. In addition to the dry dressing a light aluminum splint is applied to maintain the hand and the fingers in the position of function. As soon as the danger of lighting up the infection has passed, physical therapy and active exercises are begun so that restoration of function may keep pace with the healing of the tissues.

Summary.—The major infections of the hand—acute lymphangitis, infections of the tendon sheaths and infections of the fascial spaces of the palm, present definite and unmistakable diagnostic criteria.

Lymphatic infections should be treated conservatively and operated upon only when there are unequivocal signs of pus formation. Infections of the tendon sheaths and fascial spaces of the palm should be drained carefully and adequately as soon as the diagnosis is made.

In the post-operative care of hand infections the prevention of secondary infection, early mobilization and the maintenance of the hand in the position of function during the period of enforced immobilization are important details of treatment.

INTRA-ABDOMINAL LOCAL ANESTHESIA*

Robert P. Caron, M.D.
Minneapolis

THE purpose of this paper is to review some of the advantages, disadvantages and important technical points in the administration of intra-abdominal splanchnic anesthesia, together with the neuro-anatomy of the viscera. I am indebted to Doctor Robert Emmett Farr, with whom I was formerly associated, and to Doctor Stanley R. Maxeiner, with whom I am associated at the present time, for much of my subject matter.

INDICATIONS

There is nothing controversial in choice of anesthesia for the rugged, healthy individual, but in the chronically ill, in the aged, in cases of sepsis and in toxic states such as that due to late bowel obstruction, we believe that local anesthesia is the preferable method. Certainly, there is no one ideal anesthetic. It is not the purpose of this article to compare the limitations of spinal or the hazards of general anesthesia; each one of these forms of anesthesia is applicable to the individual case. Local anesthesia enables the surgeon to carry out his work with due deliberation and makes it unnecessary to sacrifice careful technic for speed. During the past year and one-half, we have induced over 85 spinal anesthesias and in some of the difficult cases, requiring longer procedures, the spinal anesthesia had waned before the completion of the operation, and at this stage we complemented the anesthetic by the establishment of intra-abdominal sympathetic anesthesia and infiltration of the abdominal wall with novocaine solution in order to reach our objective. In other words, a knowledge of the technic of intra-abdominal local anesthesia is an adjunct to the armamentarium of the surgeon relying on spinal anesthesia or mixed anesthesia, as recommended by Crile,[1] which depends for its efficacy on the completeness of the local anesthesia. The results obtained from the use of intra-abdominal local anesthesia are contingent upon the skill of inducing the anesthesia and also the ability to apply the special surgical technic which is necessary in order to operate successfully with this type of anesthesia. At the present time many surgeons with practically no training in the method consider themselves able to perform intra-abdominal operations under local anesthesia. They believe all there is to the method is to puddle the skin and fascia with novocaine, having no regard for anatomic landmarks, surgical strategy or the indication for splanchnic anesthesia. The chief difficulty encountered with intra-abdominal local anesthesia is the elimination of traction pain when the intra-abdominal organs are manipulated. The traction pain of normal organs is not great but it is increased when inflammatory processes are at work. Generally speaking, operations upon organs coming naturally in contact with the abdominal wall or those which can be readily brought up to it may most readily be performed, such as stomach and hernia operations. It is the establishment of anesthesia upon organs which normally lie deeper and require traction upon mesenteric attachments which we will dwell upon mostly.

DISADVANTAGES

The method cannot be used successfully in cases of sepsis where the operative field is infected. Intra-abdominal sympathetic anesthesia cannot be carried out satisfactorily in the presence of very large tumors and where inflammatory matting of viscera or organs is present. The exact state of the intra-abdominal organs cannot always be anticipated until the abdomen is opened. In operations involving acutely inflamed regions which are deep in the abdominal cavity and where there is secondary attachment of the diseased part to the posterior peritoneum with abscess formation, the blocking off of the sympathetics is technically a major procedure. In other instances, after the exposed organ to be worked upon has been manipulated and especially if the patient is not coöperative, an evisceration of bowel can readily take place even though the surrounding viscera has previously been packed away. It is this type of accident which very often discourages the use of the method. Local anesthesia cannot be used in cases of psychic incompatibility.

---

*Thesis read before the Minneapolis Surgical Society, May 21, 1931.

ANATOMICAL CONSIDERATIONS

Familiarity with the anatomy of the underlying structures and the general direction of the nerve supply of the abdominal wall is essential before one essays to adopt this method. Anatomically, operations on the abdomen are divided into two groups—those in which the operative objective involves only the abdominal wall, such as hernias, lipomas and tumors, and those in the second group, whose objective requires the opening of the abdominal cavity. It is this latter group which will be discussed.

SENSIBILITY OF THE ABDOMINAL WALL

The anterior abdominal wall including skin, fascia, muscles and parietal peritoneum receives its nerve supply from the 7th to the 12th intercostal and the ilioinguinal and iliohypogastric nerves. A few sensory fibers emanate from the parietal peritoneum through the round ligament of the liver and terminate in the region of the umbilicus. It must be remembered that this latter structure should be thoroughly infiltrated with the anesthetic solution, not only because of its sensory nerve supply but because of attachment to the posterior parietal peritoneum in the region of the liver, and traction of the abdominal wall in upper abdominal work causes indirect pulling of the sensitive posterior peritoneum. The thoracic nerves, after leaving the spinal canal, accompany the intercostal vessels and reach the anterior region of the abdomen by passing superficial to the transversalis muscle and give off branches which supply the skin, oblique and recti muscles. Other branches are given off which perforate the transversalis muscle and form a plexus superficial to the peritoneum. Thus, the abdominal wall receives branches from the lower six thoracic nerves and from the ilioinguinal and iliohypogastric nerves (Fig. 1).

THE SENSATION OF PAIN IN ABDOMINAL ORGANS DURING SURGICAL PROCEDURES

Lennander,[2] in 1901, was one of the pioneers to evolve a theory of abdominal sensations. His theories in their original forms are now considered obsolete; however, he deserves great credit for stimulating study of this problem.

Neumann,[3] in 1912, produced clear-cut experiments which are still tenable. These experiments were unknown to Kappis,[4] who independently came to similar conclusions at about the same time. Kappis' conception involves a consideration of the following facts:

"Sensory fibers leading from the lateral horns of the cord follow through rami communicantes directly to the retroperitoneal ganglia. From here the fibers follow the blood vessels to the intra-abdominal organs. In the organs, the fibers are so fine that they are practically missing and no sensibility is present. Certain regions have sufficient sensory fibers present and caliber adequate to transmit sensation of pain by proper stimulus. These regions are mesentery, lesser omentum, region of cystic, hepatic and common duct, splenic and renal vascular areas and larger vessels."

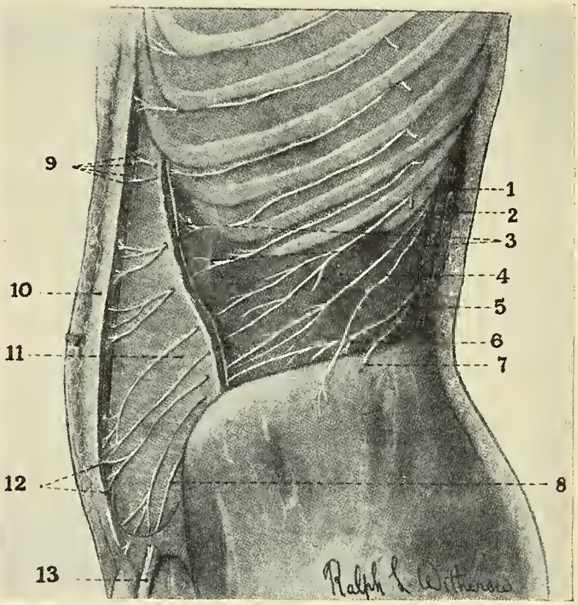

Fig. 1. Nerve supply of the abdominal wall. 1, costa XII; 2, N. intercostalis XII; 3, rami musculares; 4, M. transversus abdominis; 5, N. iliohypogastricus; 8, N. ilioinguinalis; 9, rami cutanei anteriores, N. intercostalis VIII; 10, sheath M. rectus abdominis; 11, M. obliquus internus abdominis; 12, rami cutanei anteriores, N. intercostalis XII; 13, funiculus spermaticus. (Photograph of illustration from Farr's "Practical Local Anesthesia.")

The accepted proof of this theory is the clinical result of splanchnic block or the physiological response to stimuli such as inflammatory processes as manifested by reflex muscle spasm over the segment involved. It is, at the present time, generally accepted that viscera such as liver, spleen, stomach and intestines are insensitive to pain by manipulations such as cutting or burning. Traction or clamping may elicit a diffuse, vague abdominal sensation. Upper abdominal organs such as liver, gall bladder, stomach, duodenum and spleen relay sensory impulses to the celiac plexus and from this plexus through the splanchnic nerves and rami communicantes to the dorsal cord. Vagus fibers do not transmit sensation of pain but may transmit a sensation of nausea. From the transverse colon to the rectum, nerve stimuli are gathered at the superior and inferior mesenteric and hypogastric plexuses and join the cord through the lumbar rami communicantes (Fig. 2). It is believed that cutting or burning is not a physiological stimulus and that contraction, dilatation of the viscus or muscle spasm causing acute anemia of the organs are the factors that cause spontaneous pain.

NEURO-ANATOMY AND PHYSIOLOGY OF THE VISCERA

Previous to 1914, when Kappis first published his experiments on the splanchnic mechanism in animals, there was great controversy as to the distribution of the sensory nerve supply of the abdominal cavity and the organs contained in it. Since the brilliant work of Kappis, Neumann, Lennander, McKenzie, LeMaire, Langley and others, much information has been obtained concerning the neurophysiology of the abdominal organs. The general belief at the present time, as well summarized by Detakats,[5] illustrates the following anatomical considerations:

The great splanchnic nerve is formed by branches from the sixth to the ninth thoracic ganglia of the sympathetic trunk. It has the thickness of a match and runs on both sides of the vertebral column, passes through the crura of the diaphragm on the right side with the azygos and on the left with the hemiazygos vein and joins the celiac plexus at the level of the first and second lumbar vertebræ. The lesser splanchnic nerve originates from the tenth, eleventh and twelfth thoracic ganglia and runs parallel with the great splanchnic nerve and joins the celiac but mostly the renal and suprarenal plexuses. The two semilunar ganglia are situated above the pancreas at the level of the first lumbar vertebra; they are connected with each other by a thick network of nerve cords constituting the solar plexus from which are given off the superior gastric, phrenic, hepatic, suprarenal, renal, spermatic, ovarian, aortic and superior mesenteric, hypogastric and pelvic plexuses. This network of splanchnic fibers is situated in the loose retroperitoneal space between the vertebral column and the posterior parietal peritoneum. Fibers extend from these plexuses accompanying the blood vessels to their respective organs (Fig. 3).

The meeting place of the splanchnic nerves is at the 1st and 2nd lumbar interspace. This area can be reached from behind, called the posterior route, as advocated by Kappis, or from the front before the abdomen is opened, as advocated by Wendling,[6] or after the abdomen is opened by injecting the anesthetic solution into the retroperitoneal tissue, as introduced by Braun[7] and developed by Farr.[8] It is this method which we use in our intra-abdominal work.

Practically speaking, one may summarize in general that the peritoneum of the anterior and posterior abdominal walls, pelvis and diaphragm, the latter as far as supplied by spinal nerves, is sensitive to pain. The visceroperitoneum of the stomach, intestines, omentum, gallbladder, kidneys and liver is not painful. The fundus of the uterus is not painful to stimuli but the pedicle to the ovaries and tubes as well as the attachments of the uterus are sensitive to traction. From the work of Kappis, Lennander and others, we know that the splanchnic nerves follow the blood vessels in the mesentery. Finsterer[9] claims to have described a mesentery injection in 1912. Farr, about this time, began his anterior splanchnic anesthesia with injection of the branches of the splanchnic in the mesentery and in the posterior parietal peritoneum. He established the fact that local infiltration of the abdominal wall in the line of incision could be accomplished so as to retain the anesthesia a sufficient time for ordinary laparotomy. By injecting a small amount of the anesthetic solution retroperitoneally and by surgical strategy, he has made local anesthesia of the various organs practical. With spring retractors for holding the abdominal wall well out of the field of operation, shifting the table to bring the organs worked upon into view, gentle handling of the viscera and lack of traction, he has excluded the use of general anesthesia in most abdominal surgery. The establishment of intra-abdominal anesthesia can be accomplished by injecting the solution into the mesentery, if the bowel is to be operated upon, and the supports of the adnexa in pelvic work, or by direct splanchnic anesthesia into the posterior parietal peritoneum in the region worked upon whenever this is possible.

IMPORTANT TECHNICAL POINTS

1. Again we must emphasize that familiarity with the anatomy of the underlying structures and the general direction of the nerve supply is essential.
2. Care should be taken to keep the needle point out of the large vessels and to keep the needle in motion as the injection is being made.
3. In the establishment of mesenteric or retroperitoneal anesthesia where the branches of the splanchnic are anesthetized, the important detail to consider involves the edematization of the tissues or, in other words, ballooning it by the use of only a few cubic centimeters of the solution, keeping the needle point in view, especially when the retroperitoneal structures are edematized so that the solution is not injected into large vessels.

PREOPERATIVE MANAGEMENT

Ordinarily the patient is given a preoperative sedative in order to allay apprehension: to-wit, morphin, one-sixth grain, and scopolamin, one two-hundredths grain two hours before the operation. If very apprehensive, the dose is repeated just before the operation is started. Of recent months we have been using a hypnotic of the barbituric series in the form of sodium amytal.

CHOICE OF SOLUTIONS

There are many drugs on the market at the present. During the past five years we have been using 1 per cent novocain with the addition of 3 minims of adrenalin to the ounce.

SKIN INFILTRATION

The technic of skin infiltration and abdominal wall block will not be discussed as we are all familiar with its details without further review. But there is one point of importance which should again be mentioned. In upper abdominal work the round ligament of the liver should be anesthetized. There are many methods expounded for the establishment of abdominal wall anesthesia which are all satisfactory, including that of Labat,[10] which is a block anesthesia of the thoraco-abdominal nerves, or the establishment of anesthesia by injecting solution over the line of incision as advocated by Farr, or a paravertebral injection as advocated by Kappis and others.

INTRA-ABDOMINAL ANESTHESIA

In cases in which intra-abdominal anesthesia is desired, a particular surgical technic must be adopted in order to painlessly manipulate organs. The strategy so often emphasized by Farr in order to eliminate traction and facilitate exposure is the keynote of success. The abdominal surgeon who successfully uses local anesthesia must be an opportunist.

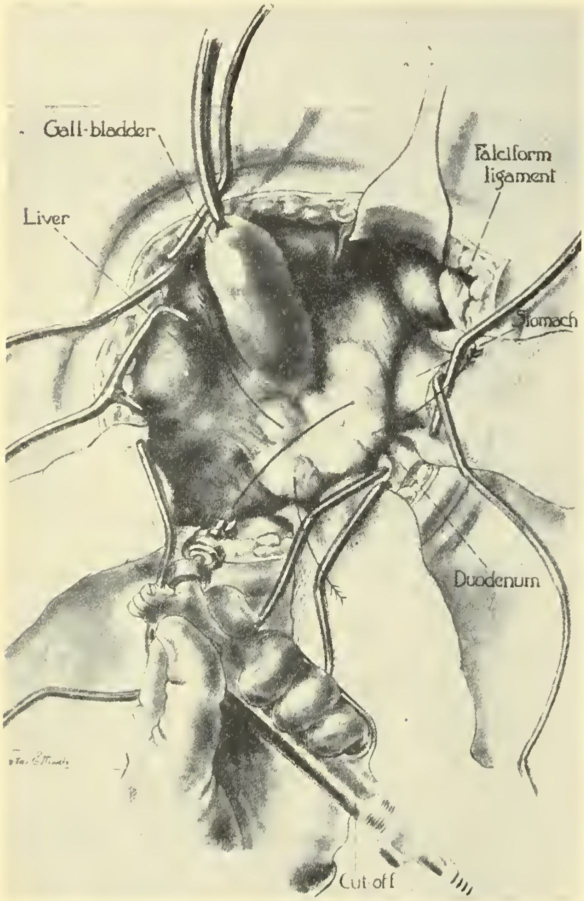

Fig. 4. Anterior splanchnic. Anesthesia technic. Surface view. Retroperitoneal injection under direct vision. Liver retracted upward, stomach and duodenum downward, giving exposure. Note anesthetic solution being introduced retroperitoneally under direct vision. (Photograph of illustration from Farr's "Practical Local Anesthesia.")

Establishment of anesthesia within the abdominal cavity is predicated upon a complete anesthesia of the abdominal wall. After the abdomen has been opened, if there is evidence of positive pressure, the anesthesia of the abdominal wall can be reinforced by injecting the solution from within outward, infiltrating the peritoneum toward the sides of the incision. This latter reinforcement of abdominal wall anesthesia is especially applicable in cases where spinal anesthesia has waned, thus completing the operation without resorting to general anesthesia.

The next important step is upward retraction in all cases so as to facilitate visualization of the organ to be worked upon in order to decrease the possibility of positive pressure and to establish splanchnic anesthesia.

RETRACTION

Proper exposure is necessary before one can begin to manipulate intra-abdominal organs painlessly. This can be accomplished by a systematic and proper introduction of automatic retractors. Routinely after the incision of the skin has been made and fascia exposed, a pair of what we call No. 2 spring retractors are placed in the fat about 1 inch from each extremity of the wound. These retractors have a point on each end which grips into the subcutaneous fat. After the peritoneum has been exposed, a larger size of the same type of retractor is placed in the wound in a like manner, retracting the fascial layers. The peritoneum is next incised and its edges held apart by one pair of No. 4 retractors which have a nonpointed loop at each end. The abdominal wall is then slowly lifted in an upward direction by a hand retractor so that the underlying organs may be exposed. Viscera can be displaced out of the operative field by the use of sponges during this procedure. The usual error committed in the placing of packs is to attempt to squeeze sponges in place without first lifting the abdominal wall.

With proper lighting and proper exposure of the known mesenteric attachments, pedicles or posterior parietal peritoneum of the area to be worked upon, splanchnic anesthesia can be started. Intraperitoneal anesthesia for some of the most practical indications for local will be discussed in detail.

APPENDECTOMY

Wherever possible, the appendix is visualized and steadied with tissue forceps while 5 or 10 c.c. of novocaine is injected into the mesoappendix. If traction on the cecum is imperative, its peritoneal attachment is ballooned up with 5 or 10 c.c. of the solution in order to establish a cecal block. In cases where the appendix is not visualized immediately, gentle manipulation with the fingers can usually locate its whereabouts and with careful packing of the surrounding viscera with moist packs, in most cases either a portion of the appendix can be brought to view or at least the cecum can be isolated so that the solution can be injected either into the mesenteric attachment or mesoappendix. The same technic applies for a cecostomy or ileostomy.

Pelvic Operations.—The round ligaments should be injected first when possible and the important point to remember is that the outer lower ends next to the peritoneal attachment are the imporant locations to be edematized with the anesthetic solution. Many operators are oblivious to this detail and repeatedly inject the solution next to the uterus rather than out near the peritoneal attachment. The ovarian and tubal pedicles and broad ligaments are then infiltrated if traction is anticipated. And wherever possible, the posterior peritoneum over the promontory of the sacrum should be exposed and anterior splanchnic anesthesia of the sacral splanchnics should be done, preferably bilaterally just beside the promontory in order not to make a vascular injection. If abdominal hysterectomy is contemplated, the above anesthesia is complemented by subperitoneal infiltration about the uterine cervix. The region of the uterine arteries is especially sensitive and a small amount of solution should be deposited in the perivascular tissue just before clamps are applied. In blocking for a panhysterectomy, the same technic as for subtotal hysterectomy is employed except that the tissues between the bladder and cervix in front and the rectum and cervix behind must be thoroughly infiltrated.

The Ovary.—The normal ovary is not particularly sensitive. However, traction should be avoided and the ovarian pedicle injected but in case of large ovarian cysts or adherent cysts, it is often difficult to inject the pedicle. In such instances, the cyst may be evacuated before delivery is attempted and suction in the cyst applied immediately in order to obviate the dissemination of possible malignant particles. Once the cyst is reduced in size, the pedicle can easily be blocked.

Cesarean section, although very infrequently done under local anesthesia, can be accomplished by simple infiltration of the abdominal wall and the avoidance of delivery of the uterus. The uterine wall is not senstive.

Upper Abdominal Operations.—Operations on the stomach lend themselves particularly to local anesthesia because of the ease of access and unusually long mesentery, the exception being infiltrating ulcers in the region of the pylorus. There is no pain in suturing, burning or cutting of the stomach. In these cases, the round ligament of the liver is blocked before the incision is made. The splanchnic region is exposed by gentle upward traction of the liver edge and the pylorus gently drawn downward. About 10 to 15 c.c.'s of the solution is introduced beneath the peritoneum in order to block the underlying splanchnics which come through with the blood vessels. The gastrohepatic omentum is ballooned up with the solution before it is divided. The sides of the large vessels are also edematized in order to anesthetize the finer splanchnic branches. Usually, clamps are avoided in order to lessen the possibility of traction. Local anesthesia in stomach operations finds its chief value because of the lessening of the possibility of operative nausea. Operations such as resections, pylorectomies and gastroenterostomies can be performed by the above technic. Gastrostomy needs no intra-abdominal anesthesia.

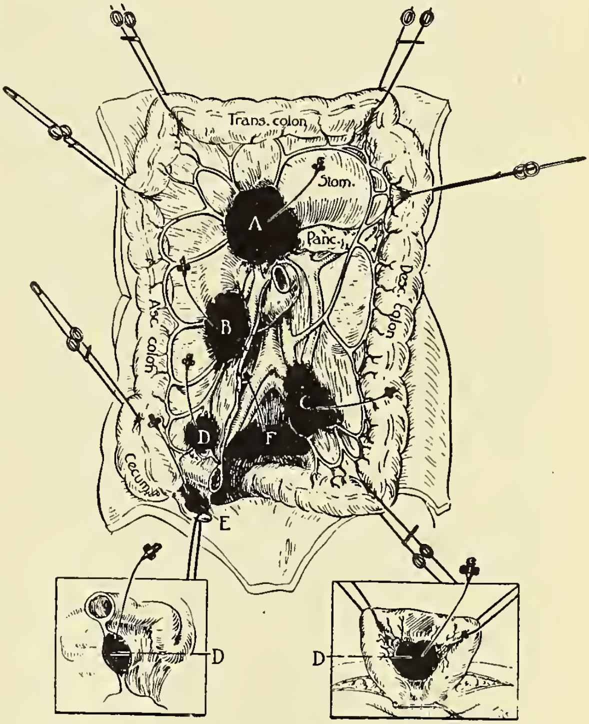

Fig. 5. The abdominal sympathetic system. Surface view. Colon eviscerated. Darkened areas show subperitoneal infiltration. A mesenteric anesthesia of transverse colon; B, mesenteric anesthesia of ascending colon; C, mesenteric anesthesia of descending colon; D, mesenteric anesthesia of small intestines; E, mesenteric anesthesia of appendix; F, anesthesia of pelvic sympathetics at pelvic brim. (Photograph of illustration from Farr's "Practical Local Anesthesia.")

Gallbladder Operations.—Gallbladder drainage can be done satisfactorily without intra-abdominal anesthesia. When the gallbladder is to be drained for stones or the ducts scooped, sympathetic anesthesia is indicated and is accomplished by infiltrating the tissues around the cystic and common ducts with a few c.c. of the solution. If cholecystectomy is anticipated, the solution is injected beneath the peritoneal coat of the gallbladder close to the liver edge and the dissection usually started at the fundus. By the time the operation has proceeded to the region of the cystic or common duct, splanchnic anesthesia has had a chance to disseminate. Cholecystectomy is not difficult if there are no adhesions and not much inflammation. In such cases, one must be especially patient and infiltrate as the dissection proceeds from the fundus towards the ducts. As the dissection proceeds downward, one can sight the region of the cystic or common duct and introduce the solution into the retroperitoneal area in order to establish a splanchnic anesthesia. The usual mistake is to proceed with the dissection rather than waiting a few minutes to give the solution time to disseminate. If traction is necessary in high-lying livers and in obese individuals where splanchnic anesthesia cannot be established satisfactorily, it would be advisable to supplement local injection by inhalation anesthesia. However, with good exposure and attention to details and technic, this contingency is very rare (Fig. 4).

The Bowel.—Before traction is applied, the mesenteric attachment of the large bowel is infiltrated along the region of the large vessels especially, keeping the needle point in view while the mesentery is being edematized (Fig. 5).

Exploratory Operations.—In cases of malignancy where doubt of operability exists, an exploration under general is often an operation of magnitude on account of the depleted condition of the patient, while with local it is no more than an inconvenience. Therefore, local anesthesia is applicable especially to exclude or confirm a certain condition by the exploratory method. However, with satisfactory abdominal wall anesthesia and a small amount of inhalation anesthesia, a most complete exploration can be done as indicated.

SUMMARY

1. Local anesthesia for intra-abdominal operations is definitely applicable in cases where general or spinal is contraindicated, in cases of spinal anesthesia where the anesthesia has waned, and is the method of choice in major abdominal procedures in all cases of prolonged debility from disease, and in the aged.

2. Familiarity with the anatomy, and particularly the neuro-anatomy, of the field of operation is essential before one attempts to adopt this method.

3. Sympathetic anesthesia can be established by injecting the solution into the mesenteries, adnexal supports, subperitoneally and perivascularly.

PRIMARY CARCINOMA OF THE BRONCHUS: REPORT OF SEVENTY-ONE CASES IN WHICH THE DIAGNOSIS WAS MADE BY BRONCHOSCOPIC EXAMINATION*

Porter P. Vinson, M.D.
Rochester, Minnesota

MALIGNANT tumors in any part of the body are often associated with secondary growths in the lungs. This is particularly true if the malignant process originates in the breast, thyroid gland or kidney. Primary malignant growths in the lung, which usually arise in one of the larger bronchi, are much less commonly observed, and until the last decade were considered rare.

In the last five years, however, there has been a rather rapid increase in the number of such cases reported in the literature; the cases have been observed at postmortem and on clinical and bronchoscopic examination. Increasing use of the bronchoscope in the study of pulmonary disease has added much to knowledge of the early manifestation of primary bronchial malignant conditions, and accurate diagnosis and appropriate treatment have resulted.

I shall review here seventy-one cases of malignant disease of the lung observed from May, 1925, to January, 1931, in which diagnosis was made by the microscopic study of tissue removed from the lumen of the bronchus at bronchoscopic examination. It is hardly necessary to record that these patients were examined under local anesthesia with a minimal amount of discomfort, and that tissue was removed without any untoward results.

Fifty-seven of the patients were men and fourteen were women. Three patients were aged from twenty to twenty-nine years; eight from thirty to thirty-nine; nineteen from forty to forty-nine; twenty-four from fifty to fifty-nine; sixteen from sixty to sixty-nine, and one patient was aged seventy-two years.

It is manifestly impossible to determine the cause of malignant disease in the bronchus or to explain the evident increase in the incidence of the lesion. It is true that many of my patients had had prolonged respiratory symptoms that were probably the result of chronic bronchiectasis, and one might conclude that local irritation was a factor in the production of the lesion. Tuberculous disease of the lungs, which has been thought to be a causative factor in malignant disease of the bronchus, had been present previously in two cases only, and preceding respiratory disease, including influenza, had been noted in forty-seven cases. Less than half of the patients (thirty-two) were smokers, and only a few smoked to excess. Eight patients gave a family history of carcinoma.

The symptoms of carcinoma of the bronchus may simulate those associated with any pulmonary disease. In many instances symptoms had been present so long that a malignant lesion was not suspected until it was discovered through the bronchoscope. Even then, it could not be distinguished from inflammatory disease in the bronchus until tissue was studied under the microscope. The symptoms referable to the respiratory tract had been present for periods ranging from ten weeks to forty years. One would expect every patient suffering from a new growth in the bronchus to cough, and yet five patients did not cough. One patient had never had any pulmonary symptoms and had come for examination because of weakness, loss of weight and pain in the legs. Sixty of the patients had had sputum, frequently purulent in character, associated with the cough. Forty-three patients had expectorated sputum containing blood in varying amounts. Dyspnea was rather marked in certain cases and seemed to be out of proportion to the amount of lung obstructed by the growth; it was present in forty-nine of the seventy-one cases of this series.

Pain in the thorax was a most disturbing symptom, and was noted by forty-seven patients. Sixty-two patients had lost weight but two had actually gained weight during the course of the disease. Stridor was present even when the lesion was situated well beyond the bifurcation of the trachea; it was noted in twenty-three of the patients. Partial blocking of a bronchus invariably results, with suppuration, and symptoms and signs produced by new growths in the bronchus are often thought to be caused by bronchiectasis or abscess. This was especially noticeable in my series of patients, as thirty-eight had had fever, ten had noted chills, five had clubbing of the fingers and thirty-one had leukocytes numbering more than 10,000. The hemoglobin of thirty-five patients was less than 70 per cent. Extension into the pleura with the development of pleural effusion is common in these cases, but in the cases of my series a diagnosis was made relatively early and the complication was observed in six cases only. In two of these the fluid was clear, in two it was blood-stained and in two pus was found in the pleural cavity.

---

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the Southern Minnesota Medical Association, Faribault, Minnesota, August 24, 1931.

Carcinomas arising in a bronchus usually produce obstruction to the lumen of the tube and limit the entrance of air into the lung beyond the stenosed area. Bronchostenosis was present in fifty-three cases and was the most frequently observed physical sign. Stenosis of the bronchus may be confused with thickening of the pleura or pleural effusion, but in the former the percussion note is not greatly impaired, whereas, in the latter, dulness or flatness is present.

Metastasis was definite in ten cases, and questionable in one case; it was usually observed in the cervical lymph nodes but was noted in the orbital cavity in two cases and in bones in three. The recurrent laryngeal nerve was involved, with resulting paralysis of the vocal cord, in four cases. Although malignant disease metastasizing to the lungs from other organs rarely produces the signs and symptoms of primary malignant disease in the bronchus, one must always consider the lesion in the bronchus to be secondary to an extrapulmonary growth.

One patient had had a hypernephroma removed eight years previously, one had had carcinoma of the bladder two years before the onset of the pulmonary lesion, and a third patient had had carcinoma of the uterus two years before the bronchial growth appeared. None of the tissue removed from the bronchial lesion resembled that of the original growth.

Roentgenographic examination of the thorax revealed evidence of a lesion in the lung in sixty-nine cases; in the other two cases the examination was considered negative. In thirty-two cases the lesion observed was thought to be inflammatory, and in one case the shadow in the roentgenogram was thought to be due to benign tumor. In thirty-six cases a roentgen diagnosis was made of primary malignant disease in the bronchus; the diagnosis was based on infiltration near the hilum of the lung extending toward the periphery as a fan-shaped lesion that is usually associated with partial pulmonary atelectasis.

Although bronchoscopy offers the most accurate method of early diagnosis of malignant disease of the bronchus, I have not been able to obtain positive evidence in about a third of the cases suspected of being malignant, because the lesion was in an inaccessible portion of the bronchial tree, or the infiltration was not associated with ulceration and a satisfactory piece of tissue could not be obtained. In many cases, negative bronchoscopic data can be explained by an erroneous clinical diagnosis. One should not hesitate to remove tissue from an infiltrating lesion in the bronchus if a malignant process is suspected, for in many instances the lesion cannot be distinguished from inflammatory disease without microscopic study of a portion of the growth.

In seventy of the cases, the diagnosis of malignant disease of the bronchus was made at the first bronchoscopic examination. In the remaining case, the patient was rather intolerant to the examination and the lesion in the bronchus to the lower lobe of the left lung was not detected until several months later, when another bronchoscopic examination was made.

In a considerable number of cases the clinical history and the general and roentgenographic data suggested the presence of bronchial malignancy, and at bronchoscopy the gross picture was similar to malignant infiltration, but tissue removed from the lesion was inflammatory, and subsequent developments have proved that the character of the disease was benign. This condition has been noted especially in cases of unsuspected foreign body of intrapulmonary or extrapulmonary origin. In certain cases in which tuberculosis involved the base of a lung the condition simulated malignant disease of the bronchus, but usually there was absence of bronchial ulceration, although in a few cases the differential diagnosis could not be made until tissue removed from the bronchus had been examined microscopically. On bronchoscopic examination, the growth can be located exactly. On the right side, the lesions were in the bronchus to the lower lobe in twenty-three cases, in the main bronchus in twenty-one and in the middle and upper lobes in two each. On the left side, the lesions were in the main bronchus in twelve cases, in the bronchus to the lower lobe in seven and in the bronchus to the upper lobe in three. In one case there was diffuse carcinomatous infiltration of the trachea and bronchi, and in another the lesion was in the trachea alone. Tissue removed from the bronchus was examined and graded according to the method of Broders. In forty cases the lesion was squamous-cell epithelioma; twenty-seven of these lesions were graded 4, twelve were graded 3 and one lesion was graded 2. In twenty-six cases the lesion was adenocarcinoma; eleven were graded 4, twelve were graded 3, one lesion was graded 2 and two lesions were graded 1. Carcinoma was graded 4 in two cases and 3 in one case. In one case the lesion was regarded as lymphosarcoma and another was not graded because a sufficient amount of tissue was not obtained for examination.

Although the prognosis in primary malignant disease of the bronchus is regarded as hopeless, one should always advise the use of radium or deep roentgen rays, except in cases in which the general condition of the patient does not permit any type of treatment. Forty-two of the patients in this series were treated with radium or roentgen rays, and as practically all were advised to have treatment, it is possible that others were treated after returning to their homes.

Ten patients were living and considered their condition much improved or cured for an average of fifteen months after a diagnosis was made at the clinic. All of these had had radium or roentgen-ray exposures, or both. Seven were failing after an average duration of life of seven months following a diagnosis, and two of these had been treated. Fifty-four patients died after an average life of six and a half months; thirty of these had been treated. Although the results of treatment could not be classified as brilliant, the fact that the condition of ten patients is improved or cured after radium or roentgen-ray exposure, one patient for four years, justifies the employment of such treatment whenever possible. At present, the operative treatment of malignant growth of the bronchus is hardly justifiable.

CONCLUSIONS

1. Primary malignant disease of the bronchus is not rare.
2. Any infiltration at the hilum or base of the lung may be the result of malignant disease.
3. Pulmonary symptoms are usually present, but in some cases they may be mild or absent.
4. Bronchostenosis is the most frequently observed physical sign of the disease.
5. Patients suffering from malignant growths in the bronchus have had pulmonary symptoms for many years, and it is possible that prolonged pulmonary suppuration may predispose to the development of carcinoma.
6. Bronchoscopy offers the only means of making a relatively early and accurate diagnosis of the presence of a malignant lesion of the bronchus, and is usually indicated in chronic pulmonary disease if tuberculosis is an unlikely etiologic factor.
7. Radium and roentgen-ray treatment has been followed by beneficial results and should be employed unless contraindicated by extensive metastasis or extreme weakness.

REVIEW OF NON-TUBERCULOUS CASES ORIGINALLY DIAGNOSED PULMONARY TUBERCULOSIS*

RICHARD M. BURKE, M.D.
Oak Terrace, Minnesota

A STUDY of adult patients sent to this Sanatorium with a diagnosis of pulmonary tuberculosis and subsequently found to be non-tuberculous was made. All patients, with a few exceptions, who are admitted, enter with a diagnosis of some form of tuberculosis. During the past five years 2,429 patients have been admitted and 2,096, or 86 per cent, had pulmonary tuberculosis. This brief study was undertaken primarily to obtain a statistical picture of the incidence and types of non-tuberculous patients encountered; and secondarily, to offer a few remarks on the problems of differential diagnosis which this review might bring to light.

About 12 per cent of pulmonary cases receive a so-called "deferred" diagnosis on admission. By this is meant that there is insufficient evidence at the time to warrant a diagnosis of tuberculosis, and implies that further study and observation will be necessary. Many of these individuals with a clinical history suggestive of tuberculosis, but with few objective findings, require several months of observation before a non-tuberculous diagnosis is justified.

In classifying these cases we use the scheme adopted by the National Sanatorium Association.[1] Diagnostic standards given for non-tuberculous cases are as follows:

1. No persistent râles in the upper half of the chest.
2. X-ray negative or showing a slight peritruncal lesion.
3. Tubercle bacilli never found in sputum.
4. Complement fixation test for tuberculosis, positive or negative.
5. No constitutional or focal reaction to the subcutaneous tuberculin test after the injection of 10.0 Mg. of Old Tuberculin once repeated. (Scale of doses—0.0001; 0.001; 0.003; 0.005; 0.01; 0.01.)
6. Constitutional reaction to the subcutaneous tuberculin test of 10 Mg. or upon repetition without focal reaction as determined by physical signs (râles) or X-rays.
7. No history of unexplained hemoptysis of a teaspoonful or more.
8. No history of unexplained pleurisy with effusion.

The group which is designated as "suspected tuberculosis" follows the above classification except that either No. 7 or 8 may be positive but not both. ("Suspects" were not classified separately, but were included under the deferred diagnosis group.)

A third group which we should at least mention are the "non-clinical" cases. They conform to the classification given for non-tuberculous cases with one exception, viz.: No. 2 reads "Parenchymal X-ray lesion not explainable by other causes." Serial chest films are of especial value here in determining whether active tuberculosis exists. Patients with non-clinical tuberculosis frequently come in with symptoms which have been falsely explained by the X-ray film. Sixty-nine cases of non-clinical tuberculosis have been sent in during the past five years, many of them with minor non-tuberculous complications which accounted for their symptoms.

TABLE I

CASES ADMITTED WITH DIAGNOSIS OF PULMONARY TUBERCULOSIS

1925-1929

Diagnosis	No.	Per cent
Pulmonary tuberculosis	1943	92.7
Non-clinical tuberculosis	69	3.3
Non-tuberculous	74	3.6
Indeterminate	10	.4
Total	2096	100.0

In Table I we see that 74, or 3.6 per cent, of the patients sent to the Sanatorium were found to be non-tuberculous. The percentage given for similar cases by other sanatoria agree closely with this figure. Various authors, among them Rist and Hamilton,[2] have felt that sanatoria often unwittingly harbor many cases not suffering from tuberculosis. This, however, is not true at present, with the improved diagnostic aids coupled with the rigid diagnostic standards

---

*From the Glen Lake Sanatorium, Oak Terrace, Minnesota. Read before the Monthly Staff Meeting of Glen Lake Sanatorium, May 19, 1930.

TABLE II

COMPARISON OF ADMISSION AND DISCHARGE DIAGNOSIS MADE AT SANATORIUM

Non-Clinical Cases		No.	Per cent	Non-Tuberculous Cases		No.	Per cent
Adm. Diag.	Pulmonary Tb.	26	38	Adm. Diag.	Pulmonary Tb.	6	8
	Non-clinical Tb.	10	15		Non-clinical	6	8
	Deferred	33	47		Non-tuberculous	2	4
					Deferred	60	80
Disch. Diag.	Non-clinical	69	100	Disch. Diag.	Non-tuberculous	74	100

exacted before diagnosis is made. The indeterminate group includes patients who deserted or were transferred to other institutions before studies were completed.

Table II gives a comparison between the admission diagnosis made here and the final diagnosis. It shows what changes the diagnoses went through and intimates that a quick diagnosis was not easy, it being necessary to defer judgment on most of these patients on admission. Many of them required three months or more of study before an opinion could be given with reasonable certainty.

In diagnosing tuberculosis, Pottinger[3] states that, "the first and most important point in the diagnosis of phthisis is to know when to suspect it." Once we suspect it, diagnosis is usually not so difficult, especially with the aid of the characteristic changes seen on the roentgenogram. The routine use of chest roentgenograms in general physical examination cannot be too strongly recommended. There is, however, a group of patients in whom little evidence can be found to support a diagnosis of phthisis from a clinical or roentgenological standpoint, yet for want of a better diagnosis these individuals are often "threatened with tuberculosis." It is this group which have long offered a real diagnostic problem and which make up the bulk of non-tuberculous cases sent to us. Such patients may have lost some weight, may have a slight temperature and so on the basis of such symptoms, plus a positive skin test, he or she is often branded as tuberculous.

In regard to these obscure cases we may paraphrase Pottinger's remark and say that here the important point is to know when to allow clinical evidence to divert our minds away from tuberculosis. It is in these patients that a thorough search should be made for the presence of some chronic or acute non-tuberculous lung infection or extra-pulmonary pathology which would explain the patient's symptoms. Failing in this, tuberculosis then may have to be re-considered; and finally it is quite possible that the patient may have no organic disorder whatever.

While one should never lose sight of the possibility of tuberculosis, it is a serious mistake to wrongly diagnose an individual as tuberculous. That it may handicap the patient both socially and physically cannot be denied. We all know that there are still people who have an exaggerated fear of anyone who has been branded as a "consumptive." And also, the possibility of making a "neuro" out of a certain number of these people exists. There are some who enjoy poor health and are able to adjust themselves nicely to fit such a diagnosis. There are others who become confirmed hypochondriacs, because of their supposed tuberculosis.

TABLE III

NON-TUBERCULOUS GROUPS

Classification	No.	Per cent
1. Apparently normal	23	28
2. Misc. extra-pulmonary conditions	29	41
3. Pulmonary disease	22	31
	74	100

We divided the non-tuberculous series into three groups as may be seen in Table III. The first group we found a bit hard to classify and we may be criticized for terming them "apparently normal." Probably some of these individuals should have received a diagnosis of nervous exhaustion or instability. Many of them gave a history of having an upper respiratory infection but usually little or no tangible evidence of respiratory disease was found. Their symptoms were much the same. They gave a history of tiring easily, general malaise, slight loss of weight and probably a dry cough; some also complained of chest pains and a slight temperature rise. In none of these individuals were any one of Brown's diagnostic points[4] fulfilled.

We do not overlook the fact that many such patients have tuberculous infection and may develop tuberculous disease later in life. Such patients, especially in the teen-age group, we should warn as to the future; but we are not justified in making a diagnosis of tuberculous disease with the evidence at hand. The majority of these individuals, many of them of the nervous, high-strung type, were found to have been living outside of their physical income and were simply tired and in a so-called run-down physical condition. They usually responded to a short period of physical and mental relaxation and later to sensible living habits.

The above condition has been described by various writers as an entity, it being termed occult tuberculosis, the tired sickness, concealed tuberculosis, etc. Some authors[5, 6] have attempted to classify these individuals as tuberculous on the basis of vague symptoms plus a constitutional or local reaction following the use of tuberculin. Making a diagnosis of tuberculous disease on such meager evidence is seldom if ever warranted.[7] Masked tuberculosis such as Norris and Landis[8] describe no doubt exists but making such a fine diagnosis with our present diagnostic aids is rather precarious. (We have had no experience with the diagnosis of pre-clinical tubercle in suspects by the Caulfield Inhibitive and T.C.F. reactions as advocated by Odgen.[9]) These individuals require painstaking and frequent examinations and prolonged observation before an opinion can be given. And then it must be admitted that a certain number of these under-par individuals resist diagnosis in spite of employing all of our diagnostic weapons. This latter class are most annoying but usually survive their physicians.

We next consider the extra-pulmonary group. Among them we find conditions which give a clinical picture of nervous and physical exhaustion, as does tuberculosis. Some of them which may simulate an early tuberculous process are: heart disease, intestinal disorders, syphilis,[10] hyperthyroidism, neurasthenia, and mouth and upper respiratory infections. Among the latter chronic latent sinusitis[11] especially deserves mention.

TABLE IV

MISCELLANEOUS EXTRA PULMONARY CONDITIONS

Diagnosis	No.	Per cent
Heart disease	8	27
Intestinal disorders	5	17
Syphilis	4	14
Upper respiratory infections	4	14
Carcinoma (esophagus) (larynx)	2	7
Arthritis	2	7
Hodgkin's	1	3.5
Hyperthyroidism	1	3.5
Actinomycosis (rib)	1	3.5
Pregnancy	1	3.5
Total	29	100

Heart disease predominated in this group with intestinal disorders ranking second (Table IV). Both functional and organic conditions were included in the latter. There were two instances of gastric ulcer. In many of these patients the underlying pathological process had given rise to few localizing symptoms so attention was not directed to it.

TABLE V

NON-TUBERCULOUS PULMONARY INFECTIONS

Diagnosis	No.	Per cent
Bronchiectasis	11	50
Bronchitis	5	23
Pulmonary abscess	2	9
Asthma	1	4.5
Empyema (non-tbc.)	1	4.5
Blastomycosis	1	4.5
Pulmonary fibrosis	1	4.5
Total	22	100.

The third and last group includes the pulmonary infections of non-tuberculous origin. Bronchiectasis was by far the most frequently encountered, with bronchitis and pulmonary abscess next in order (Table V). Bronchiectasis is frequently misdiagnosed as tuberculosis or chronic bronchitis. According to Ochsner[12] the majority of so-called bronchitis patients really have bronchiectasis. It is interesting to note that there are no cases of pulmonary malignancy in this group; in fact we have had only one case of primary pulmonary malignancy on record in a total of approximately 4,400 admissions.

In recent years suppurative pneumonitis, lung abscess and bronchiectasis have been less frequently confused with tuberculosis. Alexander[13] states that this increasing accuracy in the diagnosis of these lesions is due to "the use of iodized oil pneumograms and bronchoscopy together with a better appreciation of the etiologic factors and the tremendous value of the patient's medical history."

The value of bronchograms or pneumograms deserves special emphasis. Frequently we have patients with many clinical signs of phthisis including a productive cough but no X-ray evidence on the ordinary chest plate. In these bronchography often reveals an early bronchiectasis.

The value of a complete sputum study should also be stressed. A bacteriological examination of the sputum too often ends when no tubercle bacilli are found. It should go farther. The sputum of bronchiectasis, lung abscess, the bronchomycoses,[15] fuso-spirochetal disease,[16] asthma, etc., all tell their own story and frequently bring to light the true diagnosis.

The incidence of upper respiratory disease among the non-tuberculous lung infections is not dealt with in this paper. Suffice it to say that infections of nasal accessory sinuses were almost invariably found and appeared to be a predisposing factor in many cases, as Dunham[14] and others have pointed out.

TABLE VI

TABULATION OF LEADING SYMPTOMS GIVEN BY ALL NON-TUBERCULOUS GROUPS

Symptom	No.
Tiredness or weakness	22
Dry cough	20
Productive cough	13
Slight temperature	14
Chest pains	10
Bloody sputum	9
X-ray evidence of tb.	9
Loss of weight	8
Night sweats	6
Frequent colds	3
Bronchitis	3
Positive tuberculin test	2

A tabulation of the symptoms or findings which apparently prompted sending these patients to the sanatorium was made from the admission history. In most cases two symptoms were chosen, and in some instances only one was considered necessary to record, *e.g.*, X-ray changes supposedly tuberculous in origin. It is apparent from Table VI that a history suggestive of respiratory disease was obtained in most cases, yet in only one-third of the series was any lung or upper respiratory disease found.

COMMENT

The number of non-tuberculous patients sent to this sanatorium has been low. About two-thirds of them showed some sign of disease. A number of patients apparently were diagnosed tuberculosis merely on a "hunch" gained chiefly from the under-par appearance of the patient coupled with the absence of any demonstrable extra-pulmonary disease. While it is probably better to err on the safe side, yet a diagnosis in the absence of positive findings is seldom, if ever, justified.

Where and how to study these borderline cases is largely an individual problem, which in turn is dependent on available facilities for observation. Institutional care and study would be ideal in most cases, but this is impracticable, and so it usually devolves upon the general practitioner to render the important verdict: tuberculous or non-tuberculous.

SUMMARY

1. Among 2,096 consecutive cases sent to Glen Lake Sanatorium for pulmonary tuberculosis 74, or 3.6 per cent, were found to be non-tuberculous.
2. Classification of non-tuberculous patients:
    a. Twenty-eight per cent were classed as apparently normal.
    b. Forty-one per cent had miscellaneous extra-pulmonary disease, with heart disease first, and intestinal disorders second.
    c. Thirty-one per cent had non-tuberculous lung infections with bronchiectasis predominating.

HEALTH BUILDER NOT ACCEPTABLE

The Council on Physical Therapy reports that the Health Builder of the Sanitarium Equipment Co., Battle Creek, Mich., is claimed to be a "mechanical means of administering massage and vibratory exercise." It consists essentially of an electric motor driving an oscillating mechanism which transmits a vibratory motion by means of a belt, or applicator, to the user. The Council finds the Health Builder unacceptable for inclusion in its list of accepted devices for physical therapy because the firm advertises claims that are misleading, exaggerated or unwarranted; because the advertising and descriptive matter fails to give adequate warning of the dangers associated with its use; and because the firm uses an objectionable name for the apparatus. (Jour. A. M. A., November 14, 1931, p. 1466.)

MEAD'S BREWER'S YEAST

In the announcement of acceptance of Mead's Powdered Brewer's Yeast by the Council on Pharmacy and Chemistry (Jour. A. M. A., May 2, 1931, p. 1477) it was erroneously stated that this product assays approximately 1 vitamin B_2 (G unit) per Gm. It should have read 10 instead of 1. It was also erroneously stated that the unit of vitamin B_1 used for that amount of substance which, added to the diet of rats showing symptoms induced by deficiency of B_1 (F) would give an average weekly gain in weight of 3 Gm. for eight weeks. This should have read 11 to 14 Gm. instead of 3 Gm. Another error was that the product offers not less than 0.98 unit of vitamin B_2 (G) per gram. This should have read 10 units instead of 0.98 unit. (Jour. A. M. A., July 11, 1931, p. 103.)

THE SIGNIFICANCE OF INFRACLAVICULAR PULMONARY TUBERCULOSIS

E. H. Jorris, M.D.
Excelsior, Wisconsin

THE old doctrine and time-honored teaching that pulmonary tuberculosis almost invariably begins at the apex has, in the past eight years, been replaced by the concept of non-apical or infraclavicular infiltration as the initial adult lesion or true incipient tuberculosis. The opening shots at the old teaching came from two sources: 1. The significance, prognostic and clinical, of apical lesions was studied. Braeuning, in a study of patients with apical tuberculosis over a period of seven years, showed that only 7.8 per cent had developed progressive disease. He also showed that only thirteen per cent of his patients with positive sputum gave a history of apical tuberculosis. This report was startling, because it showed that the percentage of cases which progressed from apical to open tuberculosis was lower than the entire mortality from tuberculosis. Similar evidence was presented by Lydtin and Romberg, Redeker and Walter, Kayser-Peterson and others.

2. The actual beginning of progressive destructive tuberculosis was studied. Haudek, drawing from his extensive roentgenological experience, shows that apical lesions usually do not progress; that strictly apical cavities are rare. He, as well as Redeker, states that he has never seen the roentgenological pictures of a fibrocaseous bronchogenic tuberculosis develop from an apical focus.

With all of this strong evidence against apical lesions as the incipient stage of tuberculosis in mind, how then does tuberculosis start? This question was answered in the work of Assmann, Redeker, Wessler, Fishberg, Rhomberg, Ulrici and other prominent investigators, on the basis of the infraclavicular infiltrate as the truly incipient stage of pulmonary tuberculosis.

Before going further, I wish to recall to your minds the work of Ranke, his theory and classification of tuberculosis, and the modifications made by Redeker, which must be understood to appreciate the "new doctrine."

Ranke's three stage classification, with certain modifications, is now almost universally accepted by leading clinicians. He distinguishes three stages in tuberculosis, each one characterized by a different phase of immunity with different modes of propagation of the infection. The first stage is that which is now known as childhood tuberculosis, and includes the site of the first infection, often a Gohn tubercle, and the regional lymph nodes. It is marked by a profound change of all the tissue cells, developing after the first infection what is known as allergy. The tubercle bacilli with the highly irritating lipins contained in the envelope of the bacterium are treated by the body as any foreign body, that is, they are walled off and set apart from normal tissue. Owing to the avascularity of the tubercle, the infection is propagated mainly by the lymph vessels. At this stage the disease is therefore predominately a tuberculous lymphadenitis. Ranke's second stage begins with the first reinoculation of the allergic body. All of the tissue cells have become sensitized and the reaction is a prompt and intense local and general allergic response. The anatomical picture is that of acute inflammation with hyperemia, edema, and emigration of lymphocytes. During this stage, the infection spreads mainly through the blood stream, although other channels are open. This stage is therefore characterized by hypersensitiveness to reinfecting bacilli, by acute inflammation and by distant hematogenous metastasis. The third stage is characterized by a relative anergy and by propagation of the disease through continuity or through the visceral body ducts. This is his last and final stage and in his opinion a return to the second or primary state of allergy is impossible. Redeker points out that so rigid a classification would not account for the cyclic nature of tuberculosis. He states that the order in which the three stages follow each other, from the first infection to death or cure, is reversible as to time; and that a return to a preceding phase, particularly from the third to the second, is quite common. After the first stage, the majority of cases show alternating periods of hypersensitiveness and comparative anergy, corresponding to periods of activity and quiescence. It is plain to see that the second stage represents the most critical period in a patient's life and that the duration and degree of allergy decide his fate. The appearance, duration and intensity of the second phase of allergy depend not only upon the virulence and size of the reinfecting dose, but to a great extent on non-specific factors, as intercurrent disease, age, pregnancy, trauma and the influence of the endocrine and autonomic nervous systems.

On the basis of Ranke's conception, the isolated bronchopneumonic foci as described by Assmann, could have been foreseen. The new focus of reinfection must of necessity be inflammatory in character and could be localized in any portion of the lung to which the bacilli could gain access, either by inhaled air or by the lymph or the blood stream from an old lesion.

The new German school contends that pulmonary tuberculosis nearly always begins with a broncho-pneumonic focus in some part of the lung below the clavicle, from where it spreads by the formation of new foci to the mid-lung and the base, involving the apices at a much later period. They believe that, while late apical tuberculosis is common, incipient apical tuberculosis is extremely rare. The present diagnosis of incipient tuberculosis localized in the apices is in reality a false, late diagnosis and our treatment, not early but delayed.

In a study of 117 early infiltrates, Redeker reported the localization as infraclavicular in 58, mid-field in 38, lower field in 15, sub-clavicular in 4 and apical in 2 cases. They are described as soft, cloudy, homogeneous shadows, the size of a cherry to that of a plum, surrounded by normal lung tissue. The physical signs are usually very indefinite or entirely lacking. The subjective symptoms are equally insignificant.

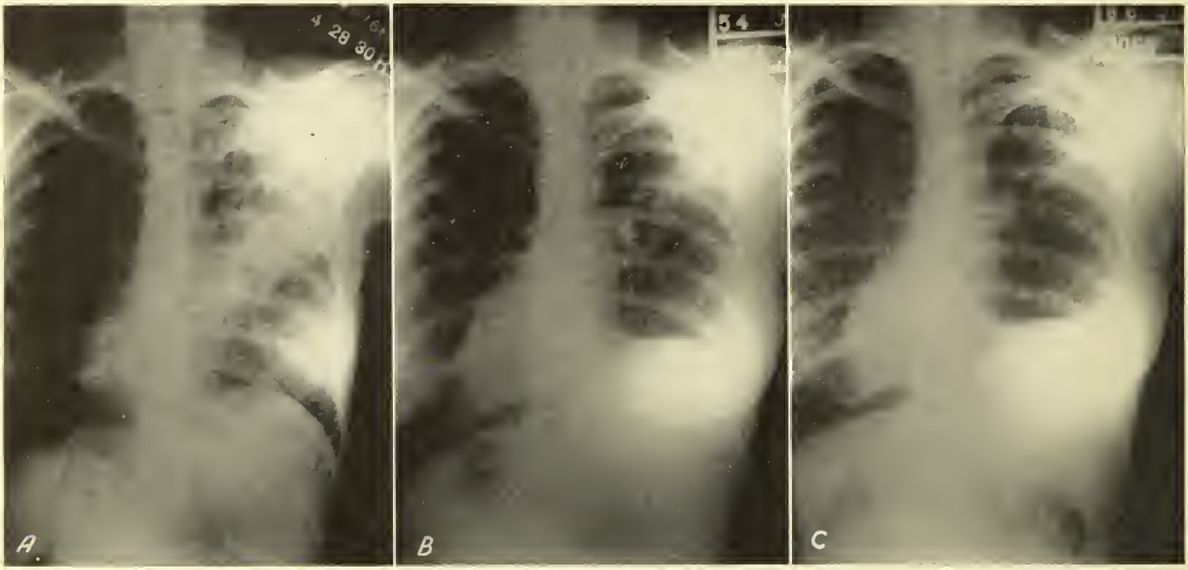

Fig. 1. Infra-clavicular lesion showing progress following early phrenic exeresis. View *A* was taken April 28, 1930; *B*, May 4, 1931; *C*, August 6, 1931.

The subject of the early infiltrate versus insidious apical tuberculosis was thoroughly studied, correlating the history of the patient with the findings on his first available X-ray plate, by Douglas, Pinner and Wolepor. From this study and that of Redeker, Assmann and other well known authorities, the following conclusions have been drawn:

1. That the "new doctrine," of which Redeker is the foremost exponent, is supported by statistical and clinical data.

2. Pulmonary tuberculosis most often begins with non-apical infiltrations, which are characterized by their instability and may progress or retrogress in a very short time.

3. Apical tuberculosis is usually a benign late form, not an occurrence of incipiency, and that rarely does an apical lesion give rise to progressive disease.

4. Progressive and destructive pulmonary

tuberculosis usually starts suddenly with exudative subapical lesions.

5. Lesions may become far advanced and cavitation develop in less than 6 months.

6. Processes leading to active progression and cavitation are usually associated with acute symptoms.

7. The physical signs and symptomatology traditionally described as characteristic for "incipient pulmonary tuberculosis," are misleading for the detection of truly incipient subapical acute processes.

8. Roentgen examination is the only method by which we can exclude pulmonary tuberculosis, which begins with non-apical infiltrates. Radiography of the chest should be used as a routine method.

9. Surgical collapse should be attempted in the treatment of infiltrates that do not retrogress spontaneously in a short time.

10. During the allergic phase, general and functional rest are strongly indicated, whereas the use of stimulating therapy, such as tuberculin, exercise, and heliotherapy, must be opposed.

11. Every effort should be made to diagnose acute infiltrations and to hospitalize patients with this type of lesion immediately.

THE TUBERCULIN TEST*

J. Arthur Myers, M.D.
Minneapolis

NEARLY everyone has at some time in the past spaded and raked a flower bed in the spring. Minute seeds were then scattered over and raked into the soil. The seeding is followed by a period of time during which it is impossible for a neighbor or anyone but the planter himself to state what kind of seed had been sown in the soil. The seeds must germinate, and even when the seedlings make their first appearance through the surface of the soil, it is impossible for those not knowing the kind of seed planted to determine the species of plant. Only after the sprout has become sufficiently large so as to present definite characteristics, can the species actually be determined.

One may liken the planting of such flower seeds in the earth to the planting of germs of disease in the human body. With many of the germs it is impossible to determine their location or their kind until they have produced changes in the tissues which characterize them. This may require days, weeks, months, and even years with some of the pathogenic micro-organisms. A few of these organisms, very soon after entering the body and before they have produced areas of disease sufficiently large to be detected, bring about changes which make it possible for us to detect their presence by biological tests. One of the best examples is the tubercle bacillus. Within a short time after the tubercle bacillus has entered the body (and found lodgment), it brings about a change which we speak of as allergy and which is very readily detected by the tuberculin test.

Tuberculin was first prepared by Koch and was used by him as a test for tuberculosis in man and animals and as a therapeutic agent. Koch did not understand tuberculin as well as we do today; so some disastrous results followed its administration as a therapeutic agent. The pendulum then swung far toward the side of disfavor. Pirquet and Mantoux in 1907 and 1908 presented methods of applying the test which were harmless. When the test was applied in Vienna and other great centers of civilization, it was found that most persons who had reached the age of fifteen years reacted positively. Therefore, except in infancy and early childhood, the test was again in disrepute.

In many parts of the world the tuberculosis picture has changed almost completely since the days of Pirquet and Mantoux. The opportunities for exposure to tubercle bacilli have been reduced so that the incidence of infection is far lower than previously. Therefore, the value of the tuberculin test has increased and is increasing every year. That the tuberculin test is one of the most accurate tests ever discovered by man may truthfully be said.

The following quotation from Dorset informs us as to the nature of tuberculin: "Tuberculin is the clear, sterile filtrate obtained from culture of tubercle bacilli on a broth medium. The broth medium is essentially nothing but meat extract to which salt and glycerine are added. The cultures of tubercle bacilli on this broth are completely sterilized by heat, and the killed bacilli are removed by filtration. The tuberculin, therefore, contains only the unused portions of the culture liquid plus any soluble substances which may have been formed in the broth as a result of the growth of the bacilli.

"Since tuberculosis is a most serious and fatal disease, it would not be unreasonable to expect that some men would claim that the tubercle bacillus, growing on broth in laboratories, would excrete into the broth poisons or toxins which would be capable of producing in healthy individuals symptoms and lesions similar to those of the disease itself. It is a well known fact, however, that all bacteria under such conditions do not produce soluble toxins or poisons. The broth on which tubercle bacilli have been grown (tuberculin) may be injected into normal animals in doses vastly greater than those used for testing purposes, without causing any ill effect whatever. With tuberculous animals, on the other hand, the case is quite different for they are extremely sensitive to the culture filtrates from tubercle bacilli (tuberculin). This curious fact has a close analogy in the peculiar sensitiveness that certain individuals exhibit to the pollen of plants. For most people this pollen is without effect, and yet it causes most distressing symptoms in hay-fever patients because they in some way have been sensitized to the pollen. The case is the same with tuberculosis and tuberculin. Infection, often to a very slight degree, is sufficient to sensitize animals to tuberculin."

---

*From the Departments of Preventive Medicine and Internal Medicine, University of Minnesota, and the Lymanhurst School for Tuberculous Children. Presented before the 78th Annual Session of the Minnesota State Medical Association at Minneapolis, May 6, 1931.

The type of tuberculin to be used for this test has been a subject of considerable discussion. At one time it was believed that a person or animal infected with the bovine type of tubercle bacillus would react positively to tuberculin made from that type of tubercle bacillus only. Experimental studies have proved that such a specificity ordinarily does not obtain. Animals infected with the avian or bovine type of tubercle bacilli will react positively to tuberculin made from the human type of tubercle bacilli. In fact, the veterinarians, who have tested many million cattle. use Koch's Old Tuberculin made from the human type of bacilli.

A great many methods of administering tuberculin have been employed. The majority of workers in the field of tuberculosis are now convinced that the intracutaneous method of Mantoux is superior to all methods known. The dilutions used for this test are simple and may be made by the physician himself or by the pharmacist. The dilution for the first test consists of one part of Koch's Old Tuberculin to nine thousand nine hundred ninety-nine parts of physiologic salt solution. One-tenth of a cubic centimeter of this solution is introduced into the layers of the skin just as one would administer the material for a Schick test. This amount of the dilution contains one-hundredth of a milligram of tuberculin. If the test is negative at the end of forty-eight or seventy-two hours, a second test is usually applied. The dilution for this test consists of one part of Koch's Old Tuberculin to ninety-nine parts of physiologic salt salt solution. One-tenth of a cubic centimeter of this solution is administered in precisely the same manner as the first test, but it contains a full milligram of tuberculin. If this test is negative, we usually feel that tuberculous infection is not present. However, some physicians prefer to continue using stronger concentrations until five or ten milligrams of tuberculin are given for one test.

The diagnostic specificity of tuberculin is evidenced by the positive reaction of animals which have first been proved negative and then were inoculated with tubercle bacilli. Good evidence is also obtained by applying tuberculin tests to members of families in homes where open cases of tuberculosis exist; then applying the test to the same number of members of families in homes where tuberculosis does not exist. Work of this kind has been done in Minnesota by such excellent physicians as Lampson and Slater. Perhaps the best evidence has been contributed by the veterinarians who, after the animals react positively to tuberculin, examine their bodies at postmortem. The high incidence of disease found in the bodies of these animals has proved beyond doubt the specificity of tuberculin.

A positive tuberculin test in the body of a human being nearly always means that somewhere in the body tubercle bacilli have found lodgment. They have multiplied and tubercles have been or are being produced. In other words, there is an area of tuberculous disease somewhere in the body. It may be no greater in size than that of a millet seed, or it may be of sufficient extent to overwhelm and take the life of its host. This area of disease, which is necessary to cause the body to react positively to tuberculin, may be completely under control or it may be progressing. It may have been present many years or it may be of rather recent origin; it may be in the lung or it may be in some part of the body very remote from the lung. The tuberculin test only informs us that the area of disease is present. The tuberculin test is not a test for immunity—it is only a test for allergy.

The tuberculin test is not infallible. Like every other biological test known to man, it occasionally fails. During the time between the entrance of the tubercle bacilli into the body and the development of allergy, which is known as the pre-allergic stage, the tuberculin test is negative. This usually is a period of from two to three weeks. However, the time varies.

In terminal cases of tuberculosis, allergy apparently decreases. The ordinary dose of tuberculin may cause no reaction, but if the dose is increased to a sufficient extent, even in such cases a positive reaction is obtained. Some believe that tuberculous lesions, particularly those of the childhood type, may, after years, become completely burned out, or perhaps walled off to such an extent that there is no communication between the products of the tubercle bacili and the adjacent tissues. Individuals possessing such lesions may lose their allergy and hence react negatively to the tuberculin test. The available evidence of such complete control of tuberculous lesions is slight.

Perhaps the convincing evidence of the value of the tuberculin test has been demonstrated by those interested in the live stock industry. The veterinarians saw early the significance of the tuberculin test. In fact, Gutman used tuberculin to test cattle in Dorpat, Russia, as early as 1891. Although tuberculin was used in this country to test cattle in 1893, the intensive and extensive campaign did not begin until about 1917. In the interval between 1893 and 1917, work preparatory for this campaign was done.

The results accomplished by the veterinarians are astounding. In 1930 alone, 12,506,198 cattle were tested with tuberculin in the United States. Almost 1.7 per cent reacted positively. In 1918, 4.9 per cent of the cattle tested reacted positively. This represents a large reduction in the number of reactors. In the State of Minnesota, fifty-five of our eighty-seven counties have reduced the number of reactors to tuberculin from approximately 7 per cent to 0.28 per cent. In the State of Wisconsin, there are certain counties where tuberculosis has been completely eradicated from cattle. For six years it has been impossible to find a single positive reactor.

From an economic standpoint the saving to this country from the work of the veterinarians has been so great that most of us cannot even conceive of the figures. Dr. H. R. Smith, Commissioner of the National Live Stock Exchange, makes the following statements:

> "If the percentage of cattle condemned for tuberculosis in the United States had been as high during 1930 as during 1916, when the campaign was started, there would have been 21,387 more cattle carcasses condemned than were actually condemned during 1930. On the basis of twenty cattle to the car and thirty cars to the train, this represents thirty-five trainloads of cattle saved from the rendering tanks in 1930 as compared with 1916.
>
> "If the percentage of hogs condemned for tuberculosis during 1930 had been as high as during 1916, there would have been 43,059 more hog carcasses condemned during 1930 than were actually condemned. On the basis of sixty-five hogs to the car and thirty carloads to the train, this represents twenty-two trainloads of hogs saved from the rendering tanks, or a total of fifty-seven trainloads of cattle and hogs saved for food.
>
> "If those cars were to be placed in one solid train, allowing forty feet, outside measurement of each car, it would represent a train thirteen and one-tenth miles long saved from the grease tanks during 1930 as compared with 1916.
>
> "A train of cattle and hogs six and eight-tenths miles long was saved from sterilization during 1930 as compared with 1916, on which sterilized carcasses the loss is approximately one-half.
>
> "Comparing 1930 with the year previous, 1929, the saving from condemnation was eight trainloads of cattle and two trainloads of hogs, or a solid train two and three-tenths miles long. Another train of cattle and hogs nearly one mile long was saved from sterilization, which product is sold as canned meat and labelled 'Sterilized.'"

The campaign has gained such momentum and proved its great value so that in 1930 the Federal appropriation was $6,361,040, while State appropriations total $12,154,226. Already two million cattle which reacted positively, together with the bacilli they contain, have been destroyed. Here is the greatest demonstration of tuberculosis control of all time. For some time we feared and fought tuberculosis in animals on the ground that it was dangerous to the human family. The scene has changed. The veterinarian is now fearing exposure of animals to tuberculous members of the human family.

In the human family we must proceed to a certain point exactly as the veterinarian does. In other words, we must adopt the area testing plan, keeping in mind that tuberculin is highly specific and that the test is harmless when properly administered. Already area testing has been practiced in a very limited way, but the procedure is gaining in favor. In Minnesota, such men as Slater and Lampson blazed the trail. The work of these physicians has been quoted in medical literature around the world. As early as 1925, Slater tested children in a rural community and found that only 10 per cent reacted positively to the tuberculin test. In the last two years, the Minnesota Public Health Association and the State Board of Control have done a great deal to stimulate interest in area tuberculin testing of human beings. The most encouraging result has been the finding of the incidence of tuberculous infection very low among high school girls and boys and even among those of college and university age. Today, the zeal of an idealist or an enthusiast is not necessary for the recommendation of area testing of human beings because the procedure has become a standard one. Chadwick of Massachusetts and later of Detroit. McCain of North Carolina, Rathbun of New York, and many others had proved the great value of this procedure before the Minnesota Public Health Association and the Minnesota State Board of Control adopted it.

The mere application of tuberculin tests is of no avail as a tuberculosis control measure. It only informs us of the incidence of tuberculous infection. The veterinarians slaughter all reactors. At this point, we cannot continue to follow the lead of the veterinarian. Our problem now becomes much more complicated than his, but we are in a position to institute a program which he could never carry out, namely, the program of education. From this point then it becomes a matter of educating the public so that the procedures recommended will be accepted. Without this education we are unable to carry on. With this education, we can proceed from the positive reactions to the source of their infection.

Tuberculosis is a communicable disease; therefore, every person who reacts positively to the tuberculin test has been exposed to tubercle bacilli. To find the source and stop it is the best known treatment for the person who already reacts positively to tuberculin. The fact that continued exposure even among adults rather frequently leads to disaster is well established. We have in mind not only the protection of the positive reactor but the protection of every person who subsequently comes in contact with that positive reactor. We also have in mind the welfare of the person who is the source Frequently such persons are found not to be ill. A small percentage of them never are ill with tuberculosis yet they are spreading bacilli so that we speak of them as carriers. Another group who are not ill now but who have tubercle bacilli in the sputum will sooner or later become ill. If their disease is detected, this illness may be prevented. Thus, it is the good of the community that takes first place in this program.

By such area testing and follow-up work, we can very quickly construct maps of townships, counties, states, and the Nation just as veterinarians have done. These maps should tell us where the foci of tuberculosis are. When this is done, we will find areas that are veritable nests of tuberculosis and other areas where very little tuberculosis exists. With this knowledge at hand we know where to concentrate our efforts. In other words, we are no longer working blindly.

But what shall be done about the child who is found to react positively to the tuberculin test? When a child is found to react positively to the tuberculin test and no evidence of tuberculous disease can be demonstrated, the question that often arises is, what explanation should be given the parents. One person says that if we tell the parents that tubercle bacilli are in the child's body, we create tuberculophobia. A physician cited the following example: "Tuberculin tests had been applied to the school children in a rural community. The parents of one child, who reacted positively, complained that when this fact was noised about among the other children, those of the same neighborhood who had been accustomed to walking to school with this child, promptly refused to even walk with him." Another physician stated that when a child in a certain community had been transferred from regular school to a special school for tuberculous children, the children of the neighborhood refused to play with him before and after school hours.

I believe that our answer to the original question, "What shall we tell the parents?" should be "Tell them the truth." Tell them that through exposure the children have taken into their bodies of the germs of tuberculosis and that we cannot determine from the tuberculin test whether these germs have been brought under control. Even if we could state that at the time the germs are under control, we cannot go further and say that they will always remain under control. We can state with safety that every child who has had a tuberculous infection, as manifested by a positive tuberculin reaction, is a potential case of clinical tuberculosis, whether it be the lungs, the bones and joints, or other parts of the body. If they are not casting tubercle bacilli from their bodies, they are not a menace to other children at the time. The consoling fact may be told them that only a very small percentage of those who react positively to the tuberculin test develop a clinical form of disease. But the unfortunate fact which we must also inform them of is that we have no way to determine which child will develop clinical disease at any time. Therefore, the only honest way out is to advise measures, such as protection from further exposure, the building and maintaining of what we call high resistance against disease, and keeping such cases under medical and nursing supervision.

The measure of primary importance is the attempt to discover and to arrest the source of infection whether it be in the home or elsewhere. This may be done by isolating the diseased members of the family or by teaching them how to prevent the spread of tubercle bacilli to others. The child's best chance for recovery is promoted when further exposure to tubercle bacilli is stopped. If exposure be allowed to continue, the infected child is in great danger. The children who react positively to tuberculin, but who have no demonstrable manifestation of disease, should be kept under observation, perhaps not strict observation, but they should be supervised and examined at least two or three times in every year. Each child who reacts positively to tuberculin and who has demonstrable disease should be kept under very close observation. If the disease is of the childhood type, the treatment required will depend upon its stage at the date of discovery. It may be very recent disease in the inflammatory stage. If so, strict bed rest may be indicated for a while, although the majority of them recover without it. On the other hand, the disease may have become latent so that lime deposits in the lungs and lymph nodes are easily demonstrated by the X-ray. The presence of lime does not by any means indicate that the disease is healed. The following statement by Dr. H. E. Robertson, Professor of Pathology, Mayo Foundation, is significant: "I am very greatly impressed with the microscopic study of these apparently healed lesions. Very many of them show evidence of some activity histologically and I am steadily being strengthened in the opinion that the tuberculous lesion in most instances constitutes a menace of renewed activity as long as the individual may live." He is inclined to believe that the above statement applies particularly to the first infection or childhood type of tuberculosis, including the involvement of the lymph nodes at the root of the lungs. Dr. Robertson also states that he frequently finds calcium deposits, caseous material, and activity histologically all in one lesion.

Therefore, these children need special attention. They should have more rest than the normal child. In addition to long hours in bed at night, they should have one or two rest hours during the day. They must receive the proper kind of food in sufficient quantities. There is danger in overlooking the fact that the child's body is growing and that he is extremely active in play; therefore, much food is required. This food must contain the vitamins, animal proteins and other properties so necessary for energy, production, growth, and repair of the body. These children have a better chance in special schools for tuberculous children than in the regular schools. In such schools they are with others of their kind who are receiving the same treatment and they do not object to the special routine. These children are potential spreaders of tubercle bacilli, inasmuch as the caseous or cheesy material in the lymph nodes may possibly find its way into the bronchial tubes, thus contaminating them with tubercle bacilli which may be spread to the bodies of others through coughing, sneezing, and expectorating. In a special school for tuberculous children, a careful watch may be kept for such developments and for the minimal stage of the adult type of disease since every child with latent childhood tuberculosis is a potential case of adult tuberculosis. For children with progressive tuberculous disease, whether it be of the childhood or the adult type, strict bed rest should be employed. If the home conditions are not favorable, most certainly institutional care should be sought.

EXTRAOCULAR PALSIES*

Gordon R. Kamman, M.D., F.A.C.P.
Instructor in Nervous and Mental Diseases, University of Minnesota
Saint Paul

Anthony Feiling[1] says, "Ocular palsies constitute a symptom of the greatest interest and importance. They are of interest because they offer a very wide field for diagnostic skill, as well as an opportunity for a study of many different diseases. They are of importance because they are not infrequently one of those early signs of disease of the nervous system which call for exact diagnosis and appropriate treatment." A detailed discussion of all the phases of extraocular palsies would be superfluous and too complex and time-consuming for a paper of this nature. It is my intention, therefore, to point out only some of the more elementary anatomical, physiological, and clinical considerations pertinent to the subject.

ANATOMY AND PHYSIOLOGY

There are seven extraocular muscles subserving movements of the eyeball. They are the levator palpebræ superioris, superior, internal, and inferior recti, and the inferior oblique, all supplied by the oculomotor or third cranial nerve; the superior oblique supplied by the trochlear or fourth cranial nerve; and the external rectus supplied by the abducens or sixth cranial nerve. The levator palpebræ superioris is the only one of the extraocular muscles that acts alone, the others always acting in pairs or groups. Therefore, all extraocular movements are associated movements and their performance depends upon the existence of central connections between the nuclei of the various cranial nerves subserving them.

The nuclei of the oculomotor nerves lie in the gray matter surrounding the floor of the aqueduct of Sylvius. The nuclei of the third and fourth nerves are almost contiguous and lie forward toward the floor of the third ventricle. The nucleus of the sixth nerve lies farther caudally, near the floor of the fourth ventricle, and is separated from the third and fourth nuclei by a definite interval. All of the nuclei are connected by a very important structure known as the dorsal or posterior longitudinal fasciculus. This bundle of fibers is responsible for the harmonious synergetic action of the extraocular muscles supplied by the various oculomotor nerves. One of its chief functions is to bring the action of the external rectus muscle of one eye (sixth cranial nerve) into relationship with the action of the internal rectus of the opposite eye (third cranial nerve). This relationship is responsible for lateral conjugate deviation of the eyes, which is one of the most important of all extraocular movements. (Fig. 1). The exact anatomical basis for upward conjugate deviation has not yet been determined definitely, but the center for this movement is thought to be in the region of the anterior corpora quadrigemina. At least, lesions in this vicinity frequently are accompanied by paralysis of upward conjugate deviation.

The centers for extraocular movements are under the control of very important supranuclear centers in the cerebral cortex, situated most probably in the second frontal convolution of the opposite side. Paralysis of this center causes deviation of both eyes toward the side of the lesion, while stimulation causes deviation toward the opposite side. Also, paralyses due to a lesion in this area are usually more or less permanent, while the reflex movements of the eyes are not affected.

CLINICAL CONSIDERATIONS

Because of the complicated anatomical arrangement of the structures concerned in extraocular movements, paralyses may result from a great variety of lesions situated in any one of a number of places. For this reason it is necessary that we have some kind of a working scheme the better to enable us to understand the pathological processes concerned when we encounter an extraocular palsy.

There are two possible ways in which to classify extraocular palsies. They may be grouped according to the anatomical location of the lesions causing them, or they may be considered according to the nature of the lesion concerned (etiologically). For the anatomical classification I will use the outline suggested by Leslie Paton.[2] According to this writer ocular palsies may be divided into three main groups with sub-groups as follows:

---

*Read before the meeting of the Ramsey County Medical Society, May 25, 1931.

I Paralysis of cerebral origin
  A. Supranuclear lesions
    1. Cortical
    2. Sub-cortical
  B. Internuclear lesions
  C. Nuclear and nerve root lesions
II Paralysis of extracerebral origin, *i.e.*, of nerve trunks
  A. Intracranial
  B. Intraorbital
III Paralysis of muscular origin

As with disturbances of function any place in the nervous system, the causative agent in oculomotor palsies may be inflammatory, vascular, neoplastic, degenerative, traumatic, or the disturbance may be due to a congenital anomaly in the structures involved.

PARALYSES OF CEREBRAL ORIGIN

Case 1.—C. V. D., a black male, aged 54, was admitted to the Neurological Service at Ancker Hospital July 10, 1930, in a comatose condition. History obtained from the relatives indicated that he had been suffering from hypertension and nephritis for a number of years. Four months previous to his admission he had had a retinal hemorrhage in the right eye. A few hours before admission, while mowing his lawn, he had suddenly fallen to the ground unconscious, breathing heavily, and frothing at the mouth. A few minutes later he vomited. He was taken into the house and seen by a physician, who sent him into the hospital, where I saw him shortly afterward. The neurological examination showed a flaccid paralysis of all four extremities with absent tendon and superficial reflexes. No pathological reflexes could be elicited. Breathing was stertorous and the left side of the face puffed out upon each expiration. Pupils were equal and regular but did not respond to light. (He had received morphine before being taken to the hospital.) Both eyes were turned toward the right. Occasionally they would move spontaneously toward the midline, and the movements of both eyes were synchronous. However, they always would come to rest in the position of right lateral conjugate deviaiton. The clinical diagnosis was massive cerebral hemorrhage in the right hemisphere involving the posterior part of the second frontal convolution, either cortically or subcortically. The patient died without regaining consciousness, and autopsy confirmed the clinical diagnosis.

In the anatomical discussion it was stated that the third-sixth nerve complex with its connecting posterior longitudinal fasciculus is under the control of a center in the cortex of the opposite side and that paralysis of this center caused the eye to turn toward that side. "The patient looks toward the side of his lesion." In the above case there was a paralytic lesion, as evidenced by the flaccid paralysis of all four extremities. The fact that there was lateral conjugate deviation of the eyes to the right indicated to us that the lesion was in the right hemisphere. This is an example of an oculomotor palsy resulting from a supranuclear lesion.

Case 2.—L. E., a single male, aged 37, was admitted to the Neurological Service of Ancker Hospital in August, 1930, suffering from blurred vision, pain in the chest, difficulty in walking, and mental confusion. There was a history of excessive alcoholic indulgence extending over a period of several months. The physical examination was grossly negative and all noteworthy findings were confined to the nervous system. The left pupil was slightly larger than the right, and both reacted sluggishly to light and in accommodation. There was moderate congestion of both optic discs. Concerning the extraocular movements, convergence and movements upward and downward were full, steady, and synchronous. However, there was paralysis of conjugate deviation to both right and left. In other words, the eyes seemed to be fixed in the midline as far as lateral conjugate movements were concerned, but that there was no paralysis of the internal recti was shown by the fact that convergence was normal. Moreover, the fact that there was no strabismus indicated the absence of a sixth nerve palsy. What really existed was a paralysis of *movement* rather than of any individual nerves. Both knee and ankle jerks were absent, there was bilateral ataxia, and slight atrophy of the calf muscles. Blood Wassermann and spinal fluid were negative.

The patient developed symptoms of a Korsakow psychosis and was committed to the state hospital for the insane. On October 31 it was reported that all his extraocular movements had returned to normal except for a fine vertical and horizontal nystagmus.

While the diagnosis in this case could not be confirmed by autopsy, the probabilities are that this patient had an alcoholic toxic-degenerative process in his mid-brain interfering with the conductivity of the posterior longitudinal fasciculus. I present it as an illustration of an ocular palsy due to an internuclear lesion.

Nuclear lesions may be divided into two groups, acute and chronic. Among the acute types are found those accompanying the various toxemias such as botulism, encephalitis, influenza, and alcoholism. Frequently one sees a nuclear ophthalmoplegia clinically, and upon postmortem examination of the oculomotor nuclei is unable to find any anatomical explanation for the paralysis. I recall a patient examined by Dr. Hammes and me a few years ago who had progressive paralysis of all of her motor cranial nerves beginning with the oculomotor group and finally involving those in the medulla oblongata. The progression, extent, and character of the paralysis indicated a nuclear involvement, yet post-mortem examination of serial sections of the brain stem failed to disclose any pathology in either the cranial nerve nuclei or in the nerve roots. In the chronic nuclear palsies one must always think of syphilis, although there are some other more rare types of involvement, such as the congenital ophthalmoplegias of nuclear origin, and the alternating nuclear ophthalmoplegias.

PARALYSIS OF EXTRA-CEREBRAL ORIGIN

Under this group of oculomotor palsies we include those due to involvement of the nerve trunks themselves, and divide them into two groups, intracranial and intraorbital.

A good example of intracranial, extracerebral type of involvement is that seen in Gradenigo's syndrome. The occurrence of this syndrome depends upon the fact that the sixth or abducens nerve passes over the tip of the petrous portion of the temporal bone within the cranial cavity. Accordingly, in mastoiditis when the infection has extended inward to produce a caries of the petrous portion, there sometimes is involvement of the sixth nerve with a consequent turning in of the eye on that side. This condition usually is accompanied by severe pain in the side of the face and up over the scalp on the affected side. This pain is thought to be due to a simultaneous involvement of the fifth or trigeminal nerve.

Basal skull fracture is a frequent cause of extracerebral, intracranial ocular palsies.

Case 3.—B. D. F., a white male, aged 38, was admitted to the Neurological Service of the Ancker Hospital in July, 1929, suffering from acute alcoholism, severe contusions and lacerations of the scalp, bleeding from the nose and ears, and a divergent squint. His past history was irrelevant, and he never had had any trouble with his eyes. He stated that he had been on a drinking party during which a fight started. He thought that somebody struck him over the head but could not remember anything until he regained consciousness in the hospital. When I saw him he still had some oozing of blood and cerebrospinal fluid from his right ear, and there was a complete paralysis of all the muscles supplied by the right oculomotor nerve. The pupil was dilated and did not respond either to light or in accommodation. The eyeball was turned outward and could not be brought toward the midline either in convergence or in conjugate movement with the other eye. There also was paralysis of the right superior and inferior recti. The neurological examination was otherwise negative. A diagnosis was made of basal skull fracture with either tearing of the right oculomotor nerve at its exit from the brain in the interpeduncular space, or involvement of the nerve by a basal hemorrhage. Unfortunately, the patient left the hospital against medical advice before sufficient time had elapsed to determine the nature of the oculomotor involvement. However, the absence of any other neurological signs indicated that the nerve was injured outside the brain substance.

Intraorbital oculomotor palsies may be single or multiple and can result from any pathological process within the orbit or at the entrance at its posterior pole of the oculomotor nerves.

Case 4 was that of a young adult woman seen in the Clinic of Dr. James Collier at Queen's Square Hospital, London. She stated that about two weeks previous to her admission to the hospital she began to have severe paroxysmal pains in the region of her right orbit. A short time later it seemed as if her right eye were bulging and it was tender on pressure. There also was pain in the right side of her forehead. Three days before her admission she began to have diplopia when looking to the right, and later on attempts to look in any direction were accompanied by diplopia. The neurological examination was negative except for a complete right ophthalmoplegia externa associated with an impairment of touch and pain sense over the right side of the forehead. The blood Wassermann was negative, and the spinal fluid was normal. A diagnosis was made of an inflammatory lesion in the region of the right sphenoidal fissure impinging upon the third, fourth, and sixth nerves, and the ophthalmic division of the right fifth nerve. The optic nerve was spared because it enters the orbit through another opening, the optic foramen. The patient was given mercury and sodium salicylate by mouth and after about ten days in the hospital she began to improve. After three weeks in the hospital she was discharged practically cured except for a very slight weakness of her right sixth nerve and a questionable hypalgesia of the right side of her forehead.

PARALYSIS OF MUSCULAR ORIGIN

One of the most frequent causes of oculomotor palsies of muscular origin is myasthenia gravis. James Taylor[3] says that about 80 per cent of the cases of myasthenia gravis that he has seen were at the Royal London Ophthalmic Hospital. Ptosis and diplopia belong to the so-called "permanent" symptoms of myasthenia gravis and may precede the weakness of the other muscles of the body by months and sometimes even years.

Case 5.—Mrs. B. S. F., white, aged 48, was referred to Dr. E. M. Hammes by Dr. George Walker of St. Paul on December 4, 1925. Her family and past histories were negative and she stated that in the spring of 1925 she began to have difficulty in swallowing and talking. Along with this there also was some weakness of the jaw muscles which came on if the patient chewed for any length of time. The weakness of the muscles of chewing and swallowing would proceed to utter exhaustion, from which they would recover after a period of rest. After thoroughly chewing her food the patient would find it difficult to swallow as "it would pile up against her soft palate." Also toward afternoon and evening the patient's voice would become muffled and she would find it difficult to make people understand what she was saying. All of her symptoms of muscular weakness would disappear when she was thoroughly rested.

Concerning her oculomotor mechanism, the patient noticed that when she became fatigued her right eyelid would droop almost to closing. Also, after reading for any length of time she would see double (fatigue of the internal recti). These symptoms would disappear after rest only to return when the patient resumed her activities. The neurological examination was entirely negative for organic signs except for some ptosis of the right eyelid. A myasthenic reaction was obtained in the muscles of the forearms. The blood Wassermann was negative and the cerebrospinal fluid was normal. The clinical diagnosis was myasthenia gravis. In this case the ocular palsies were transient and appeared after other myasthenic symptoms had been present for several months.

Another condition in which one sometimes finds oculomotor palsies of muscular origin is Graves' disease. Garvey quotes Halloway, Fry, and Wentworth, who studied the ocular signs in 100 unselected cases of goiter and found two cases of paresis of the superior oblique muscles. He also reports a case of his own in which a complete ophthalmoplegia externa preceded by some months other clinical signs and symptoms of a typical Graves' disease. Ten months after a subtotal thyroidectomy there was some improvement in the ocular signs.

The outline and case reports just presented are intended to give a simple working basis for a clinical study of extraocular palsies. Obviously all of the various types of paralysis cannot be included, and in many instances there can be no sharply defined limits between lesions affecting nuclei, nerve roots, or association fibers. Syphilis, for instance, is capable of producing an oculomotor paralysis in numberless different ways. It may affect any part of the oculomotor apparatus, and, according to Paton, is responsible for about 40 per cent of all cases of ophthalmoplegia. Other conditions, such as disseminated sclerosis, alcoholism, encephalitis, and others, may affect the oculomotor mechanisms in a variety of ways and frequently it is extremely difficult to determine clinically whether we are dealing with a pure nuclear, intranuclear, or a nerve root lesion, or whether it is a diffuse process involving several structures. Sometimes a study and proper evaluation of the concomitant signs and symptoms is of great value in differential diagnosis.

As an aid in enumerating the various clinical conditions in which we encounter ophthalmoplegias, I refer to Paton's[2] classification of ocular palsies from an etiological standpoint.

I. Acute and sub-acute ophthalmoplegias
  A. Poisons—alcohol, lead, botulism, carbon monoxide, sulphuric acid, etc.
  B. Infective agents—encephalitis, diphtheria, influenza, syphilis, etc.
  C. Trauma
  D. No etiological factor—according to Uthoff 33 per cent
II. Chronic (progressive) ophthalmoplegias
  A. An isolated lesion—monosymptomatic ophthalmoplegia externa
  B. Tabes and general paresis—about 20 per cent of all ocular palsies (Uthoff)
  C. Disseminated sclerosis—usually nerve root
  D. Bulbar palsies, progressive muscular atrophy
  E. Diabetes—most likely a neuritis
  F. Graves' disease
III. Congenital ophthalmoplegias of nuclear origin
IV. Unilateral ophthalmoplegia
V. Recurrent or alternating ophthalmoplegia of nuclear origin

The above classification is not wholly satisfactory when used simply alone. For a proper evaluation and interpretation of ocular palsies it is necessary to consider them from both the anatomical and the etiological standpoints. Accordingly, Paton's classification is extremely useful.

In this discussion no attempt has been made to delve into or expound the anatomical and physiological minutiæ of the oculomotor mechanisms. Inasmuch as there still are many controversial aspects to the subject, such an attempt would be too time-consuming and not pertinent to my purpose, which has been merely to present the clinical applications of some of the more clearly established and elementary principles involved.

RECENT ADVANCES IN THE STUDY OF THE CAUSE AND TREATMENT OF LEUKORRHEA*

E. D. Plass, M.D.
Iowa City, Iowa

LEUKORRHEA is usually due to lesions of the cervix or vagina, rarely to disease in the upper part of the genital tract. A certain few conditions in the body of the uterus, such as adenocarcinoma, submucous fibroids, and polyps may lead to an appreciable white discharge, but endometritis and salpingitis are now given slight consideration as basic pathological conditions in this connection. The former occurs only rarely, and the diseased tube probably does not discharge its inflammatory products into the lower tract. Excluding malignant conditions, endocervicitis is the most common cause of leukorrhea, while vaginal infections with the Trichomonas vaginalis and with the Monilia group of fungi represent the latest additions to recognized etiological factors.

ENDOCERVICITIS

Endocervicitis is commonly preceded by gonorrhea or by an obstetrical episode. Laceration of the cervix incident to childbearing may open the way to infection with various microörganisms of low virulence. The appearance of cervicitis in virginal women suggests that occasionally a blood-borne infection may involve the cervix. The only symptom of the condition is leukorrhea, which tends to be aggravated by the pelvic hyperemia incident to menstruation and to pregnancy, and secondarily by debilitating diseases. The cervix appears enlarged and frequently presents dilated gland structures (Nabothian follicles) on its vaginal surface. Usually there are bright red areas of erosion or eversion, extending out from the os on the anterior or posterior cervical lip, and representing patches of cervical mucosa, which has become exposed by cervical tears (eversion) or has proliferated to replace the vaginal mucous membrane (erosion). Not infrequently these areas produce contact bleeding and arouse a suspicion of malignant change, which can be eliminated only by biopsy.

The cervical glands are compound racemose in character and penetrate deeply into the body of the cervix, beyond the reach of local antiseptic applications. At most, only temporary relief can be expected from such treatment, or from douches which merely wash away the secretion already discharged from the infected glands. Consequently, these modes of treatment have been largely discarded and newer methods are advocated. The fine-wire, nasal, electric cautery is very effective in that it destroys the infected glands and thus removes the source of the discharge. With the cautery wire heated cherry-red, lineal cauterizations are made in the canal and over the exposed eroded or everted areas. After several weeks the treatment may be repeated if inspection shows that the lesion has not been completely cured. The one apparent contra-indication is acute or subacute pelvic inflammatory disease, which may become acutely exacerbated following cauterization. The surgical treatment of cervical leukorrhea is occasionally indicated: simple trachelorrhaphy for patients with old lacerations and eversion, and the Sturmdorf operation for certain persistent cases with involvement of the entire cervical mucosa. The use of the cautery for the control of an increased leukorrhea during pregnancy is debatable; it may be done gently but probably carries some risk to the continuance of gestation.

Until recently, vaginal infection, except with the gonococcus, has been largely ignored in considerations of the etiology of leukorrhea, but we are now convinced that such local conditions are frequently concerned with the production of an abnormal vaginal discharge. Many women have been accused of having gonorrhea because of a persistent vaginitis and leukorrhea, when in reality they suffered from non-venereal parasitic infections. And other unfortunates have been submitted to hysterectomy and salpingectomy without relief, when the disease was local in the vagina. Two distinct organisms—the Trichomonas and the Monilia—have been isolated from such patients, and very probably others still remain to be identified.

---

*From the Department of Obstetrics and Gynecology, State University of Iowa. Read before the Southern Minnesota Medical Association, Faribault, Minnesota, August 24, 1931.

TRICHOMONAS VAGINALIS VAGINITIS

Trichomonas vaginalis vaginitis is apparently promoted by lack of cleanliness, since clinic patients are more commonly affected than private patients, and colored women than white; but other factors must enter the picture, since very fastidious women may show the condition. The discharge is typically highly acid in reaction, of a muco-purulent consistency, creamy yellow in color, and appears foamy or frothy. Vaginal and vulval burning, itching, and smarting are common complaints, and may be more annoying than the profuse discharge. The symptoms tend to become worse during or after the menses, possibly because the reduced acidity in the vagina at this period favors the growth of the parasites. The vaginal mucosa is intensely reddened and may appear granular. Minute ulcerations are occasionally present. Digital or speculum examination may be very painful.

Diagnosis is made by examining the fresh discharge under the microscope in a hanging drop preparation or on an ordinary glass slide, the cover slip being kept from the slide by interposing two or three cotton threads. The oval parasite is recognized by its motility, which is produced by the rapid vibration of several (probably four) flagella attached to one pole. The organisms are larger than leukocytes but smaller than the vaginal epithelial cells. They do not stain easily and cannot be found in smears stained by the usual methods. Culture is possible but rather difficult, and therefore not useful as a diagnostic measure. Identification of the organisms in the vaginal discharge does not prove their causal relationship to the symptoms, since they may be harmless invaders, as certain writers have postulated, but if other etiological factors cannot be involved, the assumption is that the trichomonads are producing the symptoms. The situation is complicated by the fact that many women harbor the parasites in the vagina and yet complain of no irritation or leukorrhea. There is no evidence that the organisms ever penetrate higher in the genital canal than the vagina. They may be present in the urine.

A very similar organism, Trichomonas hominis, is commonly present in the intestinal canal, where it seemingly produces no symptoms. It has been argued that the two parasites are really identical, and that observed variations in their form and cultural activities depend upon the medium in which they grow. If such identity can be established, the source of the vaginal infection becomes quite evident, but otherwise we have no good idea of the mode of infection.

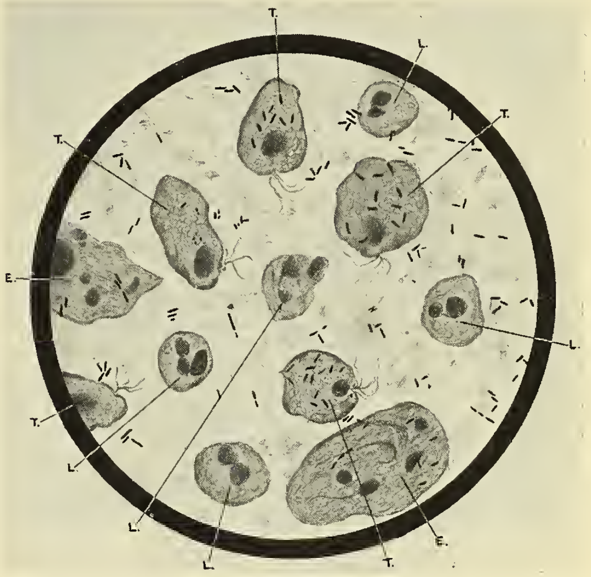

Fig. 1. Drawing of vaginal smear, showing *T*—Trichomonas vaginalis, *L*—Leukocytes, and, *E*—Epithelial cells.

Treatment is unsatisfactory. Many cases respond to various simple medicaments, while occasional patients prove refractory to every form of therapy. Among the methods most frequently advised are:

1. Acid douches—0.5 per cent lactic acid, or corresponding strengths of other organic acids. Lactic acid contraceptive jelly.

2. Drying by a current of warm air from a hair-dryer, or by packing the vagina with kaolin or some similar powder.

3. Cleansing with repeated douches, or, in intractable cases, scrubbing the vagina thoroughly with green soap.

4. Antiseptic solutions, as 1 per cent compound solution of cresol; 1 to 5,000 bichloride of mercury; 1 to 8,000 methylene blue with glycerine; half strength tincture of iodine; 10 per cent boroglyceride; and many others. None of these is specific, but all have their advocates.

With the infection limited apparently to the vagina and with the parasite so easily killed *in vitro,* it is difficult to explain the persistent character of the infection unless one assumes that the organisms burrow beneath the mucous membrane, or that an intestinal infection leads to repeated reinfections. No definite answer to this question can be given at present.

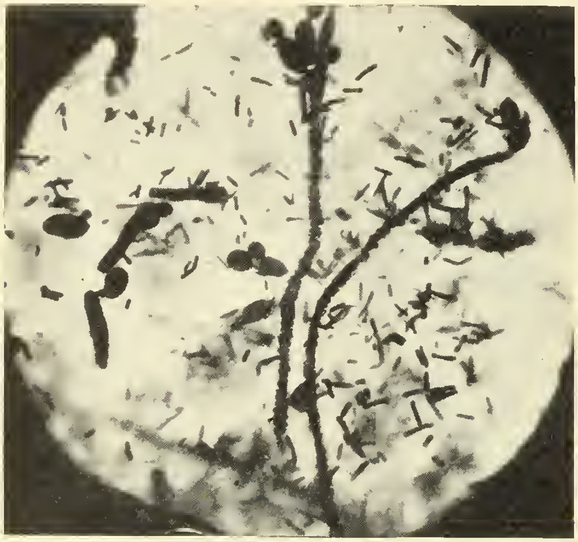

Fig. 2. Vaginal smear showing Monilia—mycelia and conidia—together with many vaginal bacilli and a few leukocytes.

MONILIA VULVO-VAGINITIS

Monilia vulvo-vaginitis is due to infection with the fungus which is commonly recognized as the cause of oral thrush in the newborn. It is predisposed to by pregnancy and diabetes, when presumably the greater acidity of the vaginal discharge favors its growth. The chief symptoms are vulval and vaginal irritation, which may be so extreme as to interfere seriously with sleep, and usually a slightly increased discharge. Examination shows the vagina markedly reddened, with the mucous membrane occasionally granular in appearance. In rare instances, white thrush-like patches of fungus are adherent to the mucosa, which bleeds slightly when the growth is removed. The vulval skin may be irritated and sometimes presents an intertrigo. Examination may be extremely painful. In the non-pregnant, the symptoms are usually worse just before the menses, when the vaginal discharge is more acid, and are relieved by the flow. Symptoms are more common in the latter months of pregnancy, but are usually completely relieved by delivery. In diabetics, insulin and dietary control of the disease frequently cause the symptoms to disappear. The organism is often present without producing symptoms: in 56 out of 156 (36 per cent) of pregnant controls, and in 14 out of 200 (7 per cent) of normal non-pregnant women. Parity seems to increase the chance of infection, but virgins may show the condition. Nothing is known of the mode of infection.

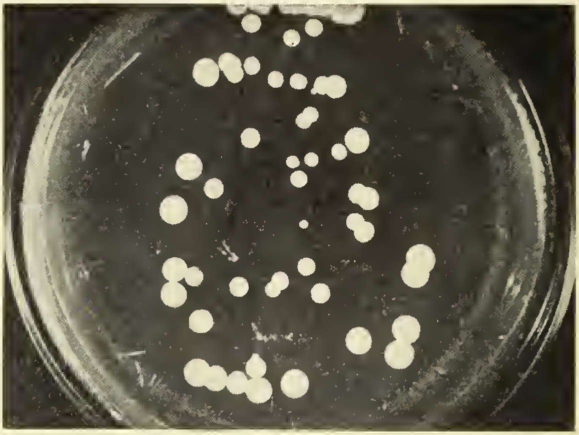

Fig. 3. Forty-eight-hour plate culture of Monilia on Sabouraud's medium.

Diagnosis is occasionally (5 per cent) possible in hanging drop preparations, when the thread-like fungus may be visible, but is somewhat easier in smears stained by the Gram method. The fungi are Gram-positive and appear in two forms, conidia, or spore forms, and mycelia, or thread-like filaments. Culture on Sabouraud's medium (glucose-peptone-agar) adjusted to a P_H of 5.5 is most certain. The organism usually grows in pure culture, although occasionally coccal or bacillary forms will survive the high acidity. Approximately 30 per cent of diagnoses can be made by the smear method, but it is much better to rely upon cultures, when laboratory facilities are available. When grown on artificial culture media, the conidial forms predominate, although old cultures in liquid media or on carrot may show many mycelia.

Treatment: Gentian violet is almost specific and is used in 1 or 2 per cent aqueous solution. The vagina is exposed with a speculum, the accumulated secretion removed with cotton pledgets, and the entire mucosa painted with the dye solution. The surrounding skin also receives a generous application. Treatment may be repeated at intervals of one or two days. In the average case, the application gives almost immediate relief from irritative symptoms, and a few treatments rid the vagina of the fungi.

Our experimental work has proved quite conclusively that this organism is the direct cause of the vaginitis. Direct inoculation with pure cultures has been followed by vaginal and vulval irritation and by an increased discharge within three or four days. Under ordinary circumstances the infection is self-limiting and the vagina becomes clear of organisms within two weeks. It would then seem that special conditions must prevail in the vagina to permit the continued growth of these yeasts, but we have little knowledge of what these conditions may be, except that diabetes and pregnancy make successful accidental or experimental inoculations much easier.

When the infection is present in a pregnant woman at the time of delivery, the child's mouth may become infected and oral thrush may develop. There is no doubt but that certain cases of sporadic thrush appear following this method of contamination. We have been able repeatedly to produce experimental thrush with Monilia cultivated from the vagina. So far, such inoculations have been successful only when the Monilia pinoyi (Castillani) is used, but possibly other forms may be concerned in rare cases of thrush.

The association of Monilia with vulval pruritus in untreated diabetics and its comparative rarity in those who are under effective treatment raises the question of the etiological relationship between the Monilia infection and diabetic pruritus vulvæ. No definite statements can be made at this time, but it seems very probable that the fungus produces the irritation, its growth being favored by the sugar-laden urine.

SUMMARY

Leukorrhea is usually due to infections in the cervix or vagina, only rarely to involvement higher up in the pelvic viscera. In the cervix, endocervicitis represents the most common lesion which is best treated with the fine-wire, electric cautery. Vaginal infections with the Trichomonas vaginalis or with the Monilia group of yeasts may lead to profuse leukorrhea and severe, persistent vaginitis. The former may be treated by a variety of methods, whereas the latter responds well to 1 per cent aqueous gentian violet applied locally.

WHEN DOES DISEASE BEGIN? CAN THIS BE DETERMINED BY HEALTH EXAMINATION?*

Charles H. Mayo, M.D.
Rochester, Minnesota

IT WOULD seem to be easy to speak positively on this subject, but disease may begin in just a few cells and spread quickly or slowly with or without sensation. Fortunately for the patient, but unfortunately for the physician when he is endeavoring to locate the beginning of disease, Nature is able to compensate in various ways for the loss of a quantity of glandular, digestive or absorptive tissue, also of organs of elimination, and, should suffering not ensue, the patient does not realize the deficiency or that he is sick, or that he soon will be appreciably sick. If one kidney is removed the other is able fully to carry on the work; not infrequently there is but one kidney at birth. This is true of all of the double organs, the parathyroid bodies, the suprarenal glands, and so forth. Naturally, this life-saving compensatory effort of Nature's mechanism adds greatly to the problem of medicine. The physician daily sees patients who come for relief of one trouble and who have various symptoms that suggest the possibility of other troubles, and unless a most elaborate series of tests is carried out for at least some of these apparently nonessential conditions, the physician may, and frequently does, miss the beginnings of essential disease. Then the patient again presents himself because of these troubles, when they become a nuisance, in many cases only to be relieved by surgical sacrifice of tissue. Examination must be within reason for the sick, or near-sick, and its extent will be based on the judgment and experience of the physician.

We cannot find out much about slowly developing chronic disease until it is distinctly chronic, which means that there is more or less destruction of tissue or of function, leading the patient to seek relief. However, we do know that in most recurring diseases, and in some chronic diseases, there is a focus if the patient is less than forty years of age, and more than one focus if the patient is more than fifty years of age. We can find out about the acute diseases of childhood, and those which occur after the entrance of organisms with inspired air or with food; some of these organisms are local in effect but sometimes they enter the blood stream and cause general symptoms.

A good many people accept illness as if it were predestined, submitting to it without thought of prevention. The average person has not yet learned the meaning of the term "positive health" and all that it implies in the way of joy of living and efficiency. If we were to adopt the criteria of the public concerning disease, "dis-ease" meaning "parting from ease," there should be some symptom, and the one symptom that all people think of is pain. If there is no discomfort they think there is no disease, unless some accident or injury has taken place, or unless there is some question of muscular trouble; even a growth or tumor may be present without the suspicion of the patient being aroused.

Anything, then, that is a parting from ease leads people to think of disease, and possibly to go to their physicians. If the disease is of their teeth, pain may send them to see their dentists. Yet how many people wait and wait, hoping that the trouble is not serious. Especially is this true of patients who have cancer. Women with a tumor in the breast will put off being examined until it has grown to considerable size or until it gives rise to other symptoms, and then it may be too late, the cancer cells have spread into the lymphatics and have localized in other regions. Adenomas, adenofibromas, or localized mastitis may be the beginning of cancer. When we see patients who have delayed to call on a physician we wonder how much good we are accomplishing by having "Cancer Week" and all the information that is given out in newspapers and by radio concerning prevention of death from this disease. We say to the public "You should come early with cancer," but unfortunately cancer in many situations does not cause symptoms. Only about 2.5 per cent of cancers involve the surface of the body. About 10.5 per cent are in the breast; a little more than 20 per cent involve the genitalia of the male and female, and more than a third involve the stomach. Patients with cancer of the colon rarely present themselves until they have a discharge of blood from the bowels or obstructive symptoms from tumor, kink, or narrowing.

---

*Read before the Minnesota State Medical Association, Minneapolis, Minnesota, May 5 and 6, 1931.

After the Wassermann test for syphilis had been discovered, I hoped that some day we might find a test of the blood that would show the presence of cancer, because the majority of cancers are internal and do not give symptoms until they are far advanced. Long since, I gave up the idea that cancer would be discovered early through any blood test, because, in watching postmortem examinations, one finds that many people who have died of pneumonia or all sorts of other troubles have had latent cancer, just as typical cancer as you can get under the microscope. Many of these were of the old Cohnheim type, consisting of a misplacement of tissue, attached to or within the capsule or structure of other organs.

I have some faith in a new test for cancer that is being tried in the west; that is, a chemical test of the urine. It was conceived on the basis that elimination through the kidneys of the waste of abnormal cellular growth might be discovered through appropriate tests. All cells cease to function the moment they become cancerous; nevertheless they have to eliminate something because of their growth, and this is thrown out in the urine. This test has not yet been placed on record. We should experiment along these lines, and from the efforts of many investigators definite results are sure to come.

Tumors of the kidney may attain great size without causing pain or bleeding. Tuberculosis of the kidney may be very far advanced before the patient has the slightest idea that he is sick. Roentgenogram of the lungs tells more in early cases of tuberculosis than does a physical examination. It often reveals all the marks of people of middle age having had tuberculosis long ago. There are the signs of healed processes, even of cavitation, but the process has been stopped for years. I would say that in 50 per cent of these patients you could not elicit any type of history that would give you the period in which the disease first appeared; in fact, many of them cannot remember when they were sick. Thus we have types of disease that do not cause recognized symptoms in their early development. Young people with tuberculosis of the lung might possibly begin to raise sputum, and we find some bacilli of tubercuosis at intervals, but how often the roentgenogram finds evidence of active tuberculosis of the lungs, and yet there are no bacilli in the sputum, or, if bacilli do appear, they are seen only at intervals.

Of 100,000 people today, 160 to 167 die annually from heart disease; it causes sudden deaths, but necropsy reveals that these people had been dying for from ten to twenty years. They had old focal infection and had had round cell infitration in infarctions of the cardiac muscle. When the nerve stimulus from within the heart happens to hit at all points on dead or nonreacting muscle the beat stops, but if one single reacting muscular element had been struck the beat would have been completed, for there was as much working muscle at that time as on the previous day.

The thyroid gland may be lacking at birth, and this gives definite symptoms. Later in life there may be dysfunction such as is seen in exophthalmic goiter, or tumors may develop and be looked on as nuisances, but not as being associated with disease until ill health sends the patients for examination.

Thousands of people have diabetes without realizing it. It may be accidentally discovered, or symptoms may urge them to seek examination. Many of these conditions are out of the realm of early recognition unless persons have physicians whose definite duty it is to look after their health by the year. All of these factors that make recognition of disease uncertain add to the difficulties of the special birthday examination which the medical profession is now urging on the public. They also show how important such examinations will be to both patient and physician.

There is room for more dentists. Just now children are being trained in the care of their teeth. People are discussing for the first time the question of the death of teeth; the conservation of teeth; disease of the jaws; the abscesses that cause no pain because the nerve is dead, a condition that may initiate trouble in any part of the body. They may cause gastric or duodenal ulcers which heal without giving the slightest symptoms, and the scars of which are found at necropsy after death from other causes, or the ulcer may even be active at the time of death without having caused symptoms. The family cannot give a particle of history that will indicate when the patient had symptoms of ulcer. So there must be latent, silent areas in the stomach that are sometimes the site of ulcers which are painless and which cause no reflex symptoms. Bacteria in diseased teeth may also cause renal stones, or diseases of the eye; Rosenow has reproduced these conditions experimentally in animals. It is probably true that local sympathetic disturbance may precede and may pave the way for the deposit of the bacteria which has been carried through the blood stream.

Patients whom we have watched year after year perhaps appear, all of a sudden, with high blood pressure. We do not know what caused it, and we have to try to find out. We have learned much about the sympathetic nervous system during the last few years. These nerves control activity of function. They control circulation by regulating the size of blood vessels. There is some control of glandular output by hormone or what might be called fluid nerves. A deficiency in the blood may be a stimulus for action. Spasm of the vessels of the leg gives pain, intermittent claudication, continued contractions, gangrene, local and acute vascular contracture, loss of fingers and toes, Raynaud's disease, chronic vascular change, and Buerger's disease. All are essentially changes in blood supply; those of great degree cause gangrene. Recently it has been suggested that the circulation of blood in the brain is also more under the influence of the sympathetic nerves than was formerly supposed, and is probably associated with spasm, sudden or slow mental attacks, and certain types of insanity. We often feel the effect of our food in its secondary effect on the sympathetic nervous system. Ducts are opened and closed by the sympathetic nerves, also by the content of food, and this action of the ducts may be held back by spasm of sympathetic origin. The intestines may become spastic; contractions may result in diverticula, and the outlets from one segment to another may become spastic. The so-called abdominal brain is in the upper part of the abdomen. In this area are the liver, pancreas, spleen, suprarenal glands, kidneys, and the stomach, all subject to many changes through many actions of nerves and hormones. Later in life defects appear in bodily sewage, which increase our discomforts. The toxins and bacterial products of the colon must largely pass to the liver through the portal circulation, but the already injured liver is unable to destroy the bacteria or to neutralize the toxic products. The openings in thick walled capillaries fail to permit the passage of the serum, with food for tissues, which may start the vascular changes later recognized as high blood pressure.

When these early conditions are recognized, what are we going to do about it? Not much. It is a great medical problem. We can now recognize these changes only when they are extensive, or when compensation fails, when, in fact, the marvellous human machine breaks and disease becomes manifest which had existed for a long time. Inherited tendencies to disease become a part of this problem, as does special and acquired immunity against infection, or resistance to cellular degeneration or hyperplasia.

If we are going to have supposedly healthy people come to us to be examined to see if they are healthy, physicians need training and more data. It is unusual today for physicians to see enough apparently normal people so that they can form a basis for recognition of early conditions and of not easily demonstrated minor illnesses. The object of all health education is to change the conduct of individual men, women, and children by teaching them to care for their bodies well, and this instruction should be given throughout the entire period of their educational life.

CASE REPORTS

FATAL REACTION FOLLOWING A TRANSFUSION OF CITRATED BLOOD*

Ernest R. Anderson, M.D.
Minneapolis

Fatalities following blood transfusions are infrequent. Blood transfusions are not entirely without danger even though the procedure is carefully controlled. The literature contains several cases of unexplainable death following a blood transfusion. A post-transfusion death should be reported in detail so that the information may be complete and be of value in the investigations of this subject.

A male, aged forty-four years, was admitted to the New Asbury hospital on Dr. R. C. Webb's service on September 11, 1931. The patient was in good health up to midnight of September 9, 1931, when he was in an automobile accident. He was riding in the rear seat of a car and at the time of the accident was thrown forward, striking the back of the front seat with his nose. He began to have hemorrhage from his nose immediately. The nose was packed that night by another physician. Hemorrhage from the nose occurred on September 10 and 11. Nasal tampons in the left nostril controlled the hemorrhage temporarily. There was swelling and ecchymosis over the nose and in both lower eyelids. Crepitation was present when the nasal bone was palpated. X-rays showed a comminuted and slightly depressed fracture of the distal portion of the nasal bone.

After entering the hospital the hemorrhage recurred and Dr. L. R. Boies was called as consultant. The nasal septum was found dislocated along the vomer ridge, with a laceration of the septal mucosa on the left side. Hemorrhage was occurring from a branch of the sphenopalatine artery at the posterior portion of the lacerated area. Posterior nasal packs had to be resorted to in order to control the hemorrhage.

On admission to the hospital his temperature was 97.8 degrees, pulse rate 84, respirations 22, blood pressure 104 systolic, 70 diastolic. The temperature remained normal until September 13, when it ranged from 101.4 degrees to 104 degrees; the pulse being 118 to 132 and respirations around 25. The nasal packs were removed on September 14. A small hemorrhage from the left nostril occurred late that evening. On the morning of September 15 the temperature was 99.6 degrees, pulse 108 and respirations 24. The patient did not have any chills with the increased temperature. Clinical examination of the lungs was normal and the physical examination was negative except for the nasal condition. The patient complained of his head feeling full and on September 13 he was drowsy.

Blood examination on September 14 showed r. b. c. —2,600,000; hemoglobin—61 per cent (Sahli); w. b. c. —29,200; the differential count was 92 per cent p. m. n., 6 per cent lymphocytes, 2 per cent large mononuclears. The patient's blood was in Group II. Urinalysis: light amber in color, specific gravity—1.020, acid reaction, trace of albumin, negative for sugar; microscopic examination of the sediment showed 0 to 2 hyaline casts, 10 to 20 granular casts, 3 to 5 pus cells and 0 to 2 blood cells.

A blood transfusion of 400 cubic centimeters citrated blood was given by gravity at 11:50 o'clock a. m. on September 15, using a donor in Group II. Sixty cubic centimeters of 2 per cent sodium citrate were used. Cross matching of the bloods was performed by Dr. Floyd Grave and Miss Grinager prior to the transfusion and there was no agglutination. The blood transfusion was preceded by 200 cubic centimeters normal saline, which was started at 11:45 o'clock a. m., and 500 cubic centimeters normal salt solution was given following the injection of the blood. The intravenous injection of the normal salt solution was ended at 12:20 o'clock p. m.

Ten minutes later the patient had a chill and at 12:45 o'clock p. m. he became irrational. The breathing became labored. There was no cyanosis and the patient expired at 2:03 o'clock p. m.

A post-mortem examination was performed at 4:35 o'clock p. m. by Dr. J. S. McCartney, the findings being:

1. Fracture of nasal bone;
2. Bronchopenumonia, found by microscopic examination;
3. Sphenoid sinusitis;
4. Cloudy swelling of the liver, kidneys and spleen.

There was no blood clotting in any of the vessels and the urine in the bladder was not blood stained.

A recheck of the matching of the bloods was performed by Miss Grinager and the bloods were found compatible.

The indications for the blood transfusion were to check and control the hemorrhage, to replace the blood loss from the continued hemorrhage and to stimulate the formation of blood elements. The hemorrhage had continued to occur even though it was temporarily controlled by mechanical means. The continued use of the posterior nasal pack seemed to be contraindicated due to the elevation of temperature, which was interpreted as being due to infection caused by intranasal manipulation and the injury.

In this case we are confronted with the question of what rôle the blood transfusion had in producing the fatal outcome. The anatomical findings at the postmortem examination are those of an infection, namely, the bronchopenumonia and sinusitis following a fractured nose. None of these conditions would be expected to produce the sudden occurrence of death.

---

*Presented before the New Asbury Hospital Staff, Minneapolis, October 7, 1931.

Reactions following blood transfusions have occurred since this procedure was instituted. The reactions may be classified as those due to using incompatible bloods, those produced by chemical substances, as anti-coagulants, and a type of reaction in which the etiology is not known and is referred to as allergic or anaphylactoid reactions.

When giving an incompatible blood the reaction occurs after giving a small amount of blood, 20 to 60 cubic centimeters, and is an indication that the transfusion should be discontinued. In 10,242 blood transfusions collected from the literature by Tiber[10] there were thirteen deaths due to the giving of incompatible blood, the total number of deaths being 22. Grouping of the blood was the method used in determining the compatibility of the bloods in the majority of the cases. This is considered sufficient by many of the writers.[1,2,3,10]

The existence of subgroups within the four major blood groups has been worked out by Guthrie and Huck.[6] When grouping is the only pre-transfusion laboratory work that is done, incompatibility of the bloods in the same group between the recipient and donor will not be detected. The use of a universal donor is advocated by Brines,[2,3] as the incidence of post-transfusion reactions is less when using Group IV donors regardless of what group the recipient is in. It has been noted that the greatest number of reactions occur when donor and recipient belong to Group II. To avoid the using of incompatible bloods, preliminary cross matching will detect the presence of incompatibility within the same group. The blood grouping of an individual remains the same throughout life.

Reactions following the different methods of blood transfusions vary. Citrated blood for transfusion developed by Lewisohn in 1915 has been used more than any other method up to date. Reactions following this method have been reported as occurring in from 10 per cent to 64 per cent[4] of the transfusions. The majority of writers report around 45 per cent. With the development of technic for the transfusion of whole blood, the post-transfusion reactions have been reduced to about 15 per cent.[4,7] In studying this question, a direct action of the sodium citrate on the red cells which promoted hemolysis was found by Drinker and Brittingham.[5]

Fatal reactions following blood transfusions in which the cause is not determinable are about .05 per cent.[3] These reactions have occurred as frequently after one method of transfusion as the other. Brines,[3] using the Unger technic, had two fatalities, one in which the donor and recipient were in Group II and in the other case the donor and recipient were in Group IV. In the second case cross agglutination was done and the findings at autopsy were negative. Using whole blood for the transfusions and having the preliminary hemolysis and agglutination tests negative, Percy[9] reports two cases of fatal hemolysis.

Using citrated blood, with the donor and the recipient in Group II, Witts[11] reports a fatality, where the cross agglutination was negative.

Anuria following a blood transfusion sometimes proves to be a serious complication. It was shown by the experimental work of Baker and Dobbs[11] that the anuria was produced by the obstruction of the renal tubules with the precipitation of blood pigment. The precipitation of the hemoglobin occurred in an acid reaction. The hemoglobin is kept in solution when the urine is alkaline and a hemoglobinuria results but a urinary suppression is avoided. It is suggested that an alkaline diuresis be established preceding a blood transfusion as a prophylactic measure.

A CASE PRESENTING UNUSUAL UROLOGIC DIAGNOSTIC DIFFICULTIES*

John L. Crenshaw, M.D.
Rochester, Minnesota

A man, aged twenty-seven years, registered at The Mayo Clinic April 10, 1931. In July, 1930, the patient had noticed a bad odor to the urine. He was given medicine by mouth without improvement. A month later while riding in an automobile he felt pain low in the back, as though someone had stuck a knife in his back. This lasted for about three hours and has not recurred. His physician advised him to stop work, which he did, although up to the time of registration he has felt as though he could work. Four months before his admission, pus was found in the urine; this continued to be present. There was no hematuria. Occasionally a stinging, gripping urethral pain occurred for a minute after urination. The stream was of good size and force, although force was needed to expel it; if it was not forced there was dribbling and pain. At times he voided fairly clear urine and in five to ten minutes, after exertion or stool, passed several ounces of thick, stinking pus. He passed urine one to two times at night. In July and August he had had a few chills and had had a little fever occasionally. Eight years before he came to the clinic, and even before that, he had had frequent epistaxis. His appetite was poor. Four years before examination, while walking on the street he suddenly lost consciousness for ten minutes. In September, 1930, while in a hot room he felt dizzy and nauseated, and went outside to vomit. The attack lasted twenty minutes. He has slept well.

---

*From the section on Urology, The Mayo Clinic, Rochester, Minnesota. Read before the Southern Minnesota Medical Association, Faribault, Minnesota, August 24, 1931.

The patient's weight was normal, 170 pounds. Systolic blood pressure was 125 and the diastolic 95 in millimeters of mercury. The pulse was 90 and the temperature 99° F. at 5 p. m. The results of general examination were negative. There was no resistance or tenderness anywhere over the abdomen or in the region of the prostate gland or kidney. On rectal examination the prostate gland was found to be enlarged graded 2, and soft and boggy. The tonsils were enlarged graded 3 and contained plugs. Pyorrhea graded 1 was present; this needed local attention only. The concentration of urea was 18 mg. in each 100 c.c. of blood. Combined excretion after intravenous injection of phenolsulphonphthalein was 60 per cent in two hours. The urine was normal in amount and the specific gravity was 1.023; it was alkaline, contained a trace of albumin, erythrocytes graded 2, and pus graded 4, but no sugar was present. Both glasses of a two glass test of the urine also showed pus graded 4. Stains of the urine for the bacillus of tuberculosis were negative. Examination of the blood, the Wassermann reaction of the blood, roentgenograms of the thorax and of the colon and urinary tract, all were negative.

Cystoscopic examination disclosed chronic cicatricial and granular urethritis graded 3 with purulent secretion graded 3 from the prostatic ducts. There was no residual urine and nothing to suggest a neurogenic disorder of the bladder. Irritability was marked, and foul, purulent cystitis with bullous edema graded 3 across the base, particularly on the left side, made it impossible to see either meatus. A cystogram showed the outline of a normal bladder without diverticulum or trabeculation.

A diagnosis was made of marked cystitis with bullous edema of the base of the bladder which was suggestive of an extravesical lesion on the left side, moderate chronic prostatitis and seminal vesiculitis with purulent secretion from the prostatic ducts, and secondary chronic urethritis. The possibilities considered at this time were: (1) prostatic or seminal vesicular abscess draining through the urinary tract; (2) vesico-intestinal fistula; (3) diverticulum of the bladder; and (4) pyonephrosis.

After prolonged irrigation of the bladder a second cystoscopic examination was made. The cystitis had improved although considerable edema remained in the left base of the bladder. Both ureteral meatuses were normal, and intravenous injection of indigo carmine returned in four minutes from both sides was of normal concentration. The left ureter was catheterized and normal urine was obtained. A left pyelo-ureterogram showed normal pelvis and ureter. Several days later an intravenous urogram was made to exclude the possibility of a second pelvis on the left, but this showed only the one normal sized pelvis on that side. The patient in the meantime was showing increasing evidences of sepsis. What, then, was the source of the pyuria?

On close observation the pyelogram of the left pelvis (Fig. 1), although normal in outline, was found to be displaced outward and downward and did not seem to compensate in size for the large, soft tissue outline of the left kidney. Therefore a diagnosis was made of complete duplication of the pelvis of the left kidney, the lower pelvis being normal, and the upper, pyonephrotic and functionless; the ureteral orifice from the upper segment was lost in the marked bullous edema of the left base of the bladder.

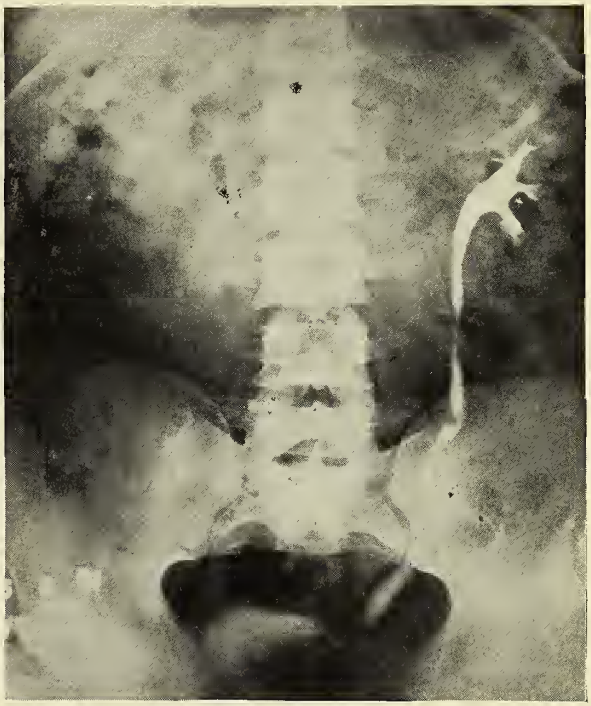

Fig. 1. Outward and downward displacement of the left pelvis.

Exploration of the left kidney May 25, 1931, disclosed complete duplication of the left renal pelvis and ureter and pyonephrosis of the upper part of the pelvis. Heminephrectomy was performed.

CONCLUSIONS

In obscure urologic conditions one must bear in mind: (1) the possibility of an anomaly and also the possibility, if the kidney is concerned, of one of its segments being functionless and therefore not outlined in an intravenous urogram and not giving a return of dye; (2) a comparison of the size of the pelvic outline with the size of the soft shadow of the kidney is often suggestive of a second pelvis being present; and (3) pyonephrosis may be present in spite of the complete absence of pain or tenderness in the region of the kidney.

ACUTE VASOSPASTIC HYPERTENSIVE DISEASE WITH TRANSITION INTO MALIGNANT HYPERTENSION

REPORT OF CASE

Charles Koenigsberger, M.D., *Mankato*
and
E. G. Bannick, M.D., *Rochester*

REPORT OF DR. KOENIGSBERGER

During the 1930 meeting of the Southern Minnesota Medical Association, Dr. Edwin Bannick and I reported an unusual case of hypertension. Certain developments in this case since our report are of sufficient interest to bring to your attention at this time. I will briefly summarize our report of last year, together with a few remarks concerning the progress of the patient since that time, and Dr. Bannick will conclude with a report of his examination made within the past few weeks.

This patient came to me in February, 1930. His age was 29 years. About two months before, he had had a severe attack of septic sore throat. During convalescence a tonsillectomy was done by his local physician. A few days after this he commenced having very severe upper abdominal colic, so severe that his physician considered biliary or renal colic. When he came to us we hospitalized him for observation and treatment. At this time the striking objective data were a vascular tension of 180/140 and a rapid heart rate with a gallop rhythm. The heart was not demonstrably enlarged. The vessel at the wrist showed very little, if any, thickening. The retinal vessels showed no sclerosis but some reduction in the caliber of the arteries. There was no retinitis. The urine and blood were normal, as were the routine tests of renal function.

During his stay in the hospital he had repeated attacks of three different types of pain:

1. Abdominal: The pain was severe, cramping in type, and unaccompanied by fever, vomiting, or physical signs of visceral disease.
2. Cerebral: The pain was that of a generalized, very severe headache.
3. Coronary: The pain was that of a typical attack of angina pectoris. Hypodermic administration of a quarter of a grain of morphine with one-hundredth of a grain of nitroglycerine invariably produced immediate relief. The use of nitroglycerine alone caused immediate cessation of pain, but the relief was very transitory unless the drug was combined with morphine.

The kidneys at no time gave trouble. The intake and output balanced well, and there was at no time evidence of any glomerulonephritis.

The eye-grounds also remained clear of exudates or hemorrhages. The heart gave a great deal of trouble symptomatically. Anginal attacks of extreme severity continued almost daily for about five weeks.

During his entire illness, the blood pressure remained systolic 150 to 180 and diastolic 110 to 140, and on April 26, when I last saw him in the office, the reading was 170/120.

This, then, is a case of acute diffuse vasopastic disease following a streptococcic throat infection characterized by striking involvement of the splanchnic, cerebral, and cardiac vessels.

From the first I considered the existence of malignant hypertension, but the lack of retinal findings or renal insufficiency precluded this diagnosis.

During April, 1931, a little more than a year later than the time covered by our report, I saw this patient again. At this time he was apparently in relatively good condition. He had gained about 40 pounds in weight and felt, in general, fairly well. He had very little headache or pain of any sort. He did, however, have a little pain around the heart on exertion. He was able to walk four or five miles slowly without special fatigue. Physical examination was about as before although the blood pressure was 200/150, the artery in the wrist showed a little more thickening, and the urine contained some albumin with a few hyalin and leukocytic casts but no blood. The examination of the retina showed irregularity of the lumen of the arteries. Notching was present, but there were no hemorrhages or exudate. The blood chemistry was normal; an electrocardiogram showed no significant changes.

At this time Dr. Bannick said to me that he would like to see this patient; I, therefore, asked that he report to Dr. Bannick, which he did about three months later. Dr. Bannick will report his findings at that time.

REPORT OF DR. BANNICK

The case presented by Dr. Koenigsberger is the most unusual example of acute vasospastic hypertensive disease that I have ever seen. I have never seen a case in which the symptoms were so severe, nor could I find a record of one in the literature. The acute hypertension associated with toxemia of pregnancy is similar in many ways, but the extremely severe abdominal cramps, and the terrific angina pectoris are practically unheard of among patients as young as this man. The diagnosis, therefore, was correctly made, not from personal experience or from study of the literature, but by exclusion. Since then, the patient has developed classical malignant hypertension with associated renal injury, all of which merits further interest and consideration.

When I first saw him, in consultation, February 21, 1930, he was in a critical condition. Nephritis was easily excluded by the persistently normal urine, by the normal results from tests of renal function, and by the absence of edema and anemia. That the hypertensive phenomenon was acute was suggested by the history and the facts that the heart was not enlarged, there was no retinitis, and no demonstrable arteriosclerosis either in the radial or retinal vessels. A diagnosis was made of acute vasospastic hypertensive disease, and treatment was given accordingly. The ultimate prognosis was guarded and the immediate prognosis was grave, although the patient's relatives were assured that, if the vasospasm could be relieved, at least temporary recovery might take place. As Dr. Koenigsberger has noted, after several weeks of rather severe symptoms the acute crises subsided, and the patient was dismissed from the hospital. The biopsy of the pectoral muscle done shortly after this for study of the arterioles disclosed a normal ratio of wall to lumen; the diameter of the lumen was approximately twice the thickness of the wall, and at first glance the arterioles seemed normal. Closer analysis revealed some increase in the nuclei in both intima and media and suggested that a reaction of some sort was going on in the wall of the vessel, but the arteriolar study definitely confirmed the previous impression that the hypertensive phenomenon was not of long standing (Fig. 1).

---

*Presented before the annual meeting of the Southern Minnesota Medical Association, Faribault, Minnesota, August 24, 1931.

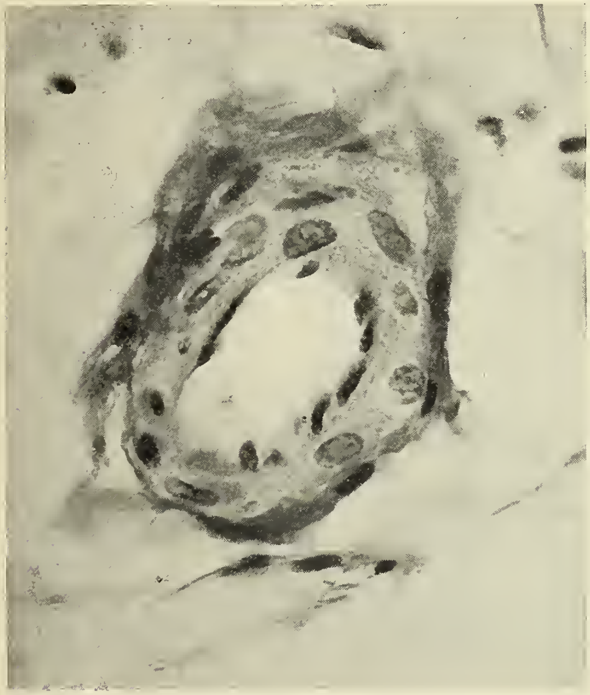

Fig. 1.

Dr. Koenigsberger reported that about a year later, or five months ago, the patient's condition had not changed much, although there were some signs of arteriosclerosis and increasing hypertension with some albuminuria, but when the patient reported at the Clinic on July 27, 1931, a considerable change in the findings was noted. Albuminuria was graded 2 to 3; the urine did not contain blood, but a few casts were seen. Excretion of phenolsulphonephthalein was 45 per cent in two hours. There was no anemia. The concentration of urea was 20 mg. in each 100 c.c. of blood, and of sulphates 6.03 mg. in each 100 c.c. of serum. Blood pressure was 225 systolic and 160 diastolic, and a record of the blood pressure for twenty-four hours showed that it stayed persistently high even at rest. The patient's heart was now definitely enlarged (graded 1 to

Severe streptococcic sore throat—followed by tonsillectomy.

2). In the electrocardiogram, among incidental findings was evidence of marked left ventricular preponderance, and a diphasic T wave in Lead I; gallop rhythm was still present. Considerable arteriosclerosis was now easily demonstrated, graded about 3 in the radial arteries and graded 2 to 3 in the retinal vessels. There was a type of retinitis typical of malignant hypertension with bilateral edema of the disks, sclerosis of the vessels, and exudates and hemorrhages. The albuminuria, the slight reduction in excretion of phenolsulphonephthalein, and the slight but definite elevation in the concentration of serum sulphates at this time suggested definite renal involvement and early renal insufficiency. The great disproportion between these renal findings, and the marked evidence of hypertensive and vascular disease, suggested strongly that the renal insufficiency was the result of arteriolar disease and vasospasm, and not of glomerulonephritis.

This is all the more convincing when note is taken of the repeatedly negative urinary findings in the presence of increasing cardiovascular and hypertensive disease. Another biopsy was obtained of the pectoral muscle at this time for further arteriolar study and for comparison with the previous biopsy. In this specimen, too, striking changes were seen. The ratio of wall to lumen now was as 1 to 1, showing that the thickness of the wall of the arterioles was practically twice that seen at the previous biopsy. There was marked increase in the number of nuclei in the intima and media (Fig. 2), and some of the arterioles were completely closed, apparently by intimal proliferation (Fig. 3). A diagnosis was made, therefore, of diffuse arteriolar disease, with malignant hypertension and early renal insufficiency, and the prognosis is extremely poor.

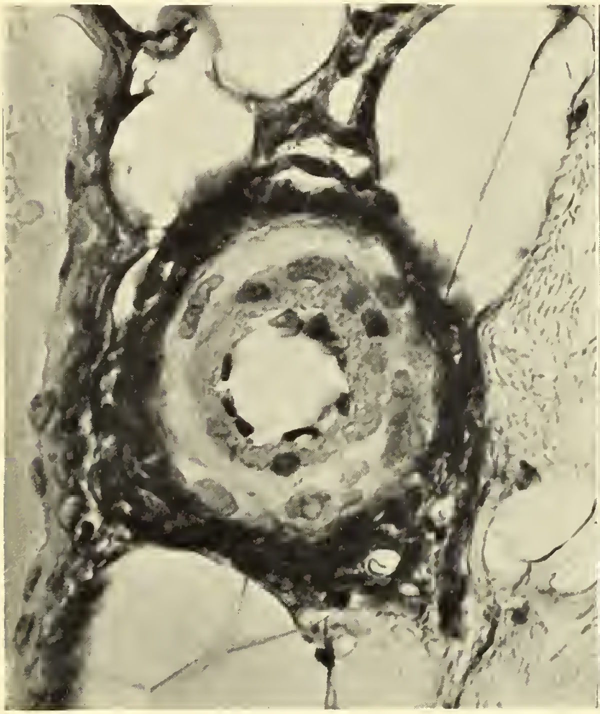

Fig. 2.

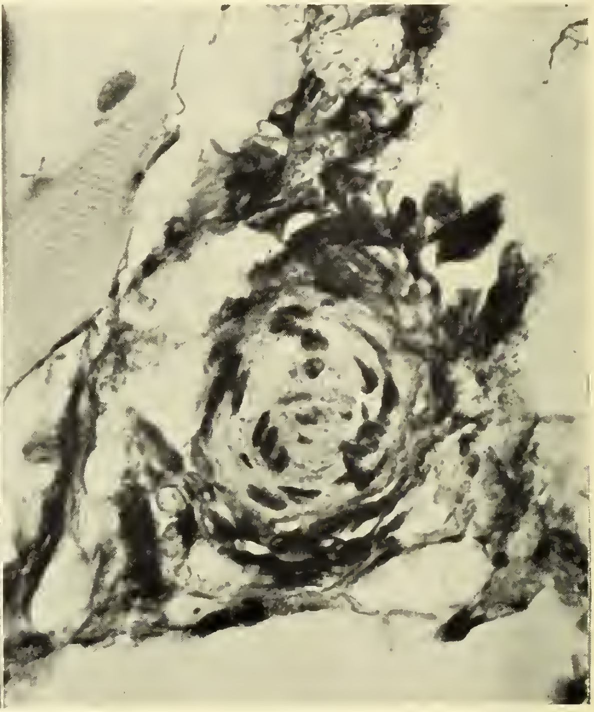

Fig. 3.

In conclusion, then: (1) development of malignant hypertension with albuminuria and early renal insufficiency came as a result of arteriolar injury and vasospasm, and not as a result of glomerulonephritis; (2) marked arteriolar involvement was proved by study of biopsy of pectoral muscle; (3) vasospasm was the chief factor at the onset, and preceded demonstrable significant arteriolar disease; (4) the diffuse vasospasm involved arteries as well as arterioles, as suggested by the angina pectoris and abdominal crises, although my impression is that angina pectoris in cases like this is not all due to coronary spasm but also to acute cardiac strain; and (5) the history of the onset suggests acute streptococcic infection as the chief etiologic factor.

PRESIDENT’S LETTER

IT IS an established custom that the President of the Minnesota State Medical Association write an open letter each month to the members for publication in Minnesota Medicine.

In this, my first letter, I want to thank the profession of the State from the bottom of my heart for the honor bestowed upon me. Born in this state and living amongst you since graduation, my shortcomings must be known to many and I wonder that I have been so signally honored. The medical profession of Minnesota has always been in the vanguard of medical progress, a fact that makes the responsibility of the office greater. My first plea is Doctor Sogge’s final plea, that all members read the columns of Minnesota Medicine closely, not only for its scientific value but for the information it contains concerning the economics of medicine that are looming up so prominently on our horizon.

Our Association is a prosperous, active, and vigorous organization. My efforts will be directed toward holding fast to the present high standards and increasing in any way possible the usefulness of the society to the members. Already plans are well started for the annual meeting this year to be held in Saint Paul, May 23, 24 and 25. Bear these dates in mind and plan to be there for the Committee on Scientific Assembly are preparing a program that will be one no member can afford to miss.

The year 1931 was full of worries, and many problems confront the people of the United States. The medical profession as an integral part of the social and economic structure of the country must share in good times and bad times. The type of medical service rendered the people is second to that of no other nation and has been administered in a democratic and independent manner free of governmental interference—typically American. The medical profession has not only fostered but sought the type of governmental aid that will enhance this service as evidenced by State Boards of Health, State Licensing Boards, the establishment of hospitals for chronic conditions such as poor crippled children, the mentally sick, the blind, deaf and the tuberculous, the burden of which must be borne by the society as a whole.

A bureaucracy may start out to be beneficial, but easily becomes questionably beneficial and inefficient. Bureaucratic medicine is sure to lead to an inferior type of medicine when it attempts to take care of the ordinary run of the ills that the general population is subject to.

There is not the slightest doubt in my mind that medicine as it has been and is practiced today in the United Statees is threatened if the plan as outlined by the Veterans’ Bureau is carried through to fulfillment. Needless to say, we all want the sick or injured veteran to have the best our country can offer. If the facts were known by the people concerning the high cost of the building, equipping, maintaining these hospitals, and providing care for the patients, they would question the expenditure of the vast sums required. There appear to be ample beds in civilian hospitals to take care of any overflow above the present capacity of the Veterans’ Hospitals. It is high time that these facts were known and it is the duty of organized medicine to do its best to aidindisseminating such information. Our profession may be accused of selfish motives but its past record of unselfish devotion toward the eradication of disease and the care of the sick or injured without thought of compensation whenever necessary is adequate answer.

Our taxation system is faulty in that only a small number are made to feel that they are partners in the enterprise of running our country. It looks, however, as though a day of reckoning were at hand. More people must pay direct taxes and consequently will be in a receptive mood for economics. We must not fail to point out forcibly to them the great expense of any such undertaking as that outlined by the Veterans’ Bureau and boldly question the type of medical service that will be rendered. Two past presidents of this association are on the recently appointed legislative committee of the American Medical Association, C. B. Wright and Herman Johnson. That committee is gathering information and advocating measures that will be in line with American policies. An editorial entitled, “State Medicine and 4,000,000 Veterans” in the last number of Minnesota Medicine is well worth reading.

OXYGENATION

The factor of anoxemia in pain production in coronary disease and the sequences in coronary thrombosis and obstruction is now accepted. Barach* has recently discussed the favorable influence upon certain congestive types of myocardial failure after the prolonged inhalation of an atmosphere containing 35 to 45 per cent of oxygen. The scant elevation of 3 to 5 per cent in arterial oxygen saturation seems to account for the patient's enhanced comfort, freedom from pain and protracted dyspnea and an increase of the carbon dioxid in the blood. In like manner, it appears that sloughs and ulcers in thrombotic varicosities are strikingly healed by McPheeters' method, whereby with the application of rubber sponges, with suitable bandages, the patient's muscular effort in walking brings oxygenated arterial blood into the areas. Thus, it would seem that normal tissues promptly suffer when deprived of oxygen and die if the lack is prolonged. Oxygen is needed for energy development and waste disposal.

In terms of this outlook, physicians should observe the basis of the work done by Professor Otto Warburg, which has given him this year the Nobel Prize in Medicine. His studies of blood ferments and oxygen conveyance, as well as the tracing of the events in plant cell photochemical synthesis, have drawn attention to his exactitude in measurements and an attempt to link up biology with the newer physics, even as chemistry has been absorbed by it. His work has further led him into a study of the relationship of oxygen to the metabolism of malignant or cancer cells. He has shown that, like anaërobic bacteria, they can live without oxygen, securing their pabulum from sugar destruction. From this no one draws the conclusion, on account of this common attribute, that cancer may have a bacterial origin; rather does this fact suggest that both bacteria and cancer cells are primitive entities. It recalls the interesting popular writings of Haldane, where in terms of circulation and oxygen availability he explained the limitations of such varied organisms as beetles and elephants, establishing the rôle of oxygen availability in determining both the physiologic capacity and morphologic attributes.

THE LEGION'S ATTITUDE TO THE SHOULDERS RESOLUTION

We are reproducing an editorial which appeared in the December number of an American Legion publication known as the *"Forty and Eighter"*:

THE LEGION DIFFERS WITH THE DOCTOR

The American Medical Association has opened fire on the Legion hospitalization program for disabled veterans. In opposition to the Legion plan for giving all disabled veterans needed hospital treatment in government hospitals, the Association, through its *Bulletin*, suggests a plan for disability and hospital insurance for veterans with which they could pay for private treatment in civilian hospitals. Study of this plan shows that it would be much more costly to the government and the results for the veterans in all probability would be less satisfactory.

---

*Barach, Alvan L.: Therapeutic Use of Oxygen in Heart Disease. Annals of Internal Medicine, October, 1931, 5:428.

The average cost of caring for a veteran in a government hospital is $3.84 per day, according to Watson B. Miller, chairman of the Legion's National Rehabilitation Committee, while the average cost of caring for a veteran in a civilian hospital under contract is $4.59 per day, or nearly a dollar a day more. In the civilian hospitals many additional charges are made such as for surgeons' and internists' services, nursing, operating room, drugs, etc., making the actual per diem cost very much more than in government hospitals.

All Veterans' Bureau Hospitals are approved by the American College of Surgeons, which means that the practice of medicine in these hospitals is according to the standards set up by this body. This fact does not apply to all civilian hospitals. Very few Neuropsychiatric and Tuberculosis hospitals are approved by the American College of Surgeons. This is very important because so many of the disabled veterans are being hospitalized for tuberculosis and neuropsychiatric diseases. Where would these men go for proper care if the government hospitals were not open to them?

Civilian hospitals from many standpoints are not in position to care for disabled veterans as economically or as effectively as government hospitals. The Legion must continue to differ with the opinion of the American Medical Association as expressed in its *Bulletin* and continue to support the Legion program of hospitalization for all disabled veterans in government hospitals.

This expresses the opinion of certain members of the Legion regarding the change in the method of hospitalization of war veterans as embodied in the Shoulders Resolution.* That there would not be a unanimous acceptance by the Legion of this change in policy was a foregone conclusion. As a matter of fact, however, many Legion Posts, after having the all around advantages of the change explained to the members, have approved the proposal. If the majority of the Posts favor the change, Congress is more than likely to accede to the Legion's wishes.

If Secretary Mellon's proposed increase in Federal income tax becomes effective there will be a lot more taxpayers interested in governmental economy in the future. Comparative figures as to per diem cost in government and private hospitals are not available. Most private hospitals have more or less endowment in the form at least of buildings and equipment and are not run at a profit so that it does not seem likely that the government can furnish the same hospital care for a less per diem cost. The important consideration from an economy standpoint is that the present program of the Veterans' Bureau will necessitate the construction of many Veterans' hospitals to provide the necessary hundred thousand additional beds. This is obviously a much more expensive program than utilizing the already existing private hospitals.

There are plenty of private hospitals which have received the approval of the American College of Surgeons, if the Legion wishes to limit the care of veterans to approved institutions.

It is true that there are not sufficient beds in private tuberculosis and neuropsychiatric hospitals to care for veterans thus afflicted. Most individuals needing such care are at present provided for at public expense by the individual states. If the veterans prefer federal to state care for such of their number as need it, this should make no difference to the taxpayers.

The Shoulders plan does not propose a remedy to meet a situation affecting the medical profession alone. There is in fact no provision in the Shoulders plan for remuneration of the doctor by the government. Each community has funds invested in its hospitals. Are new government hospitals to be built to the detriment of these community institutions? How are the taxpayers going to react to such extravagance? This matter is a vital one for many so-called private hospitals.

From the standpoint of the professional service secured by the veteran, will he voluntarily choose an unknown government doctor instead of the private doctor he knows personally or by reputation?

There is evidently a minority in the Legion bent on convincing the others that government care is superior to care in private rospitals under private physicians. Members of the medical profession should be interested in this most important problem so threatening to private practice. Many doctors are members of their local Legion Posts and can exert an influence locally in favor of a change so important not only for the veteran but for medical practice, hospitals and the taxpayer.

---

*Full information regarding the Shoulders Resolution is contained in the *A. M. A. Bulletin* for October, 1931.

MERCIFUL MURDER

A Danish woman deliberately gives her mother an overdose of medicine and kills her. The mother and daughter both believed the painful illness incurable, the mother had failed in an attempt at suicide and the daughter, to save her mother from the penalty of suicide in the next world, took upon herself the duties of judge, jury and executioner. And then it developed that the mother's affliction was gallstones and presumably could have been cured.

Such loose thinking, in the guise of advanced thought, should probably be ignored. This is, however, not the first reported instance of the kind. We are reminded of the surgeon son in the English novel "Sorrel and Son" who similarly assisted his father, suffering from an incurable cancer, out of this world as an act of mercy. It is difficult to judge the motive of an author in apparently approving such an act. We suspect sensationalism. Certainly an overemphasis was placed on an emotional reaction rather than straight thinking.

If a daughter has a moral right to put her mother out of misery, a mother has the same right with respect to her mentally deficient or crippled child. The state should also have the same moral right to execute idiots and the feeble-minded as well as criminals. While such a procedure would be an easy solution of a serious economic problem, it certainly would not meet the approval of an enlightened civilization.

The physician only too frequently encounters a patient for whom death would seem a blessing for all concerned. The judgment of any individual or group of human beings, however, is not infallible. Not rarely is the diagnosis of the best medical minds wrong. The supposedly permanently insane person recovers his sanity, the apparently non-viable newborn babe decides to live and eventually proves to be a genius, the incurable cancer patient lives many years to die of another malady.

Who would be eager to seek the services of a physician who might consider it his moral right to dispatch him to eternity if the diagnosis justified?

It seems to be ofttimes forgotten that pain can be largely relieved and nature is frequently capable of performing seeming miracles. We know something about the prevention and cure of conditions that so frequently make life unbearable. Much has to be learned, however, particularly in this field of prevention, before it can be applied. In the meantime the problem must be met with the present methods without resort to murder.

MEDICAL CARE OF THE POOR

At the Secretaries Conference January 23, 1932, we plan to have a symposium on "Medical Care of the Poor." This subject has created a good deal of interest throughout the State and, of course, has acquired added importance on account of the present depression. Doctors in many parts of the State are finding that their present relations with the various boards of County Commissioners are unsatisfactory. Some counties are making arrangements similar to those that have been made in Iowa, and some have been using a plan similar to that used in Polk County, Wisconsin.

We are planning to have a discussion as to the availability of these and other plans in Minnesota. In order that you may know the present law in Minnesota as a basis for your discussions, the extracts printed below are published. Please read them carefully and discuss them with the secretary of your county society so that he may come to the Conference with some definite ideas.

Mason's Statutes—Minn. 1927—3174—*Board to Appoint Physician.*—The board shall appoint one or more practicing physicians to be physicians of the poor who shall hold office during the pleasure of the board, and receive such compensation as it may from time to time determine. If more than one be appointed, the order of appointment shall prescribe the district in which each shall act, and none shall be required to act outside of his district except in case of urgency. When directed by a member of the board or by the overseer, such physician shall attend upon and prescribe for any sick poor person in charge of the overseer, and also on written direction of a member of the board shall attend upon and prescribe for any sick poor person who is entitled to receive support or relief from the county. If immediate treatment of any person who has been declared a county charge be required, any licensed physician who may prescribe for or treat him before the arrival of the county physician shall be paid therefor. He shall at once notify the county physician who shall thereupon take charge of the case. Within thirty days thereafter, he shall file with the auditor a verified report, showing the name and residence of the patient, the day and hour when called, the distance traveled in going to such place, the nature of the disease or injury, the service performed, the time when the county physician was notified and took charge, and the amount claimed as compensation. The auditor shall present such report at the next meeting of the board, which shall allow reasonable compensation.

(1501) /3084/ 25—259; 95—201, 103 + 1023

Minn. Reports—Vol. 25, P. 259. 9/20/78.—A contract of employment, made by a single county commissioner with a physician, for professional services to be rendered to a sick pauper entitled to relief from the county of such commissioner, is unauthorized by the provisions of Gen. St. C. 15, and not obligatory on the county.

" . . . . A county commissioner has no authority to employ, upon the credit of his county, a physician not thus appointed (by the board); and if he does, the unauthorized appointment will create no liability against the county. Though the plaintiff in this case may have acted in good faith in relying upon the certificates and the requests therein contained, this furnishes no ground for his claim against the county, for the law imputes to him full knowledge that the officer with whom he dealt had no authority in the premises."

Minn. Reports, Vol. 95, P. 201. June 16, 1905.—Where the town supervisors are required to provide for the care and support of the poor therein, and have no regular physician to attend its paupers, and a pauper suffers from an accident which requires the immediate attention of a surgeon, who renders services to relieve the necessity, he may recover reasonable compensation from the town, although he had not been requested by the authorities to attend the patient.

Committee on State Health Relations.
Theodore H. Sweetser, *Chairman.*

OF GENERAL INTEREST

Dr. J. A. Roy was recently elected mayor of Red Lake Falls.

Dr. Morris Greenberg has located at Robbinsdale, Minnesota, where he is doing general practice.

Dr. W. E. Richardson, Pipestone, has moved to Phillip, South Dakota, where he will engage in general practice.

Dr. C. M. Robilliard has been appointed to succeed his father, the late Dr. W. H. Robilliard, as physician to the State School for the Deaf at Faribault.

Dr. C. H. Sherman announces the opening of offices at 720 Lowry Medical Arts Building, Saint Paul, for the practice of surgery.

Dr. A. H. Parks was elected Chief of Staff of Asbury Hospital, Minneapolis, at the recent annual meeting of the staff members.

Dr. J. R. Kuth and Dr. M. H. Tibbets, Duluth, addressed academy members on "X-ray Interpretations of Orthopedic Conditions of the Spine."

Dr. Eskel Erickson, formerly of Garretson, South Dakota, has purchased the practice of Dr. L. N. Casney at Halstad, Minnesota.

The tenth anniversary of the founding of Lymanhurst school for tuberculous children, Minneapolis, was celebrated by a program given at the school Wednesday, December 2.

Dr. Henry L. Ulrich, Minneapolis, was elected president of the Minnesota Society of Internal Medicine at its last meeting in November. Dr. Moses Barron, Minneapolis, was elected secretary-treasurer of the organization.

Dr. Edwin J. Simons of Swanville was awarded the 1931 prize of $250 offered each year by the Minnesota Society of Internal Medicine to the practitioner of medicine in the state who has made the most valuable contribution to medical knowledge. The monograph submitted by Dr. Simons was on primary carcinoma of the lung.

The American Board of Ophthalmic Examinations will hold an examination in New Orleans on Monday, May 9, 1932, at the time of the meeting of the American Medical Association. Application blanks may be secured from the secretary, Dr. William H. Wilder, 122 South Michigan Avenue, Chicago, and should be submitted at least sixty days before the date of examination.

The Minnesota State Medical Association and the Minnesota State Hospital Association will conduct joint 1932 sessions in Saint Paul, May 23 to 25. The meeting, which will mark the seventy-ninth anniversary of the state medical association and the thirty-third of the hospital organization, will be the first time the two groups have convened together. Scientific sessions will be conducted jointly.

At the annual meeting of the Interurban Academy of Medicine, an organization of Superior and Duluth physicians, held Wednesday, November 18, 1931, Dr. V. E. Ekblad, Superior, was elected president for the ensuing year. Dr. Ekblad succeeds Dr. George L. Berdez, Duluth.

Dr. Mario Fischer, Duluth, was named vice-president; Dr. H. A. Sincock, Superior, secretary and treasurer, and Dr. P. S. Rudie, Duluth, censor.

Dr. Harry P. Ritchie, St. Paul, was elected president of the Western Surgical Association at its recent meeting held in Denver. He succeeds Dr. Carl E. Black of Jacksonville, Illinois, who will take Dr. Ritchie's place as recorder. Dr. Clifford W. Collins of Peoria, Illinois, was elected first vice president; Dr. Edward L. Gilcreest, San Francisco, second vice president; and Dr. Frank R. Teachenor, Kansas City, secretary-treasurer. For a number of years Dr. Ritchie was secretary of the organization and when the duties of this office were divided among secretary, treasurer and recorder, Dr. Ritchie became recorder, with supervision of publications.

The American Association for the Study of Goiter again offers an award of $300 for the best essay based upon original research work on any phase of goiter presented at their annual meeting in Hamilton, Ontario, Canada, June 14, 15, and 16, 1932. It is hoped this offer will stimulate valuable research work, especially in regard to the basic cause of goiter.

Competing manuscripts must be in English and in the hands of the Corresponding Secretary, J. R. Young, M.D., Rose Dispensary Bldg., Terre Haute, Indiana, not later than March 15, 1932.

The first award of the 1931 Kansas City, Missouri, meeting was given Dr. Bruce Webster, Presbyterian Hospital, New York City, "Studies in the Etiology and Nature of Simple Goiter as produced Experimentally in Rabbits."

Dr. C. O. Rice, Minneapolis, among others, received honorable mention for his paper on "Life Cycle of the Thyroid Gland in Minnesota."

On the evening of December 17 a complimentary banquet was tendered Dr. John L. Rothrock of Saint Paul at the Minnesota Club by members of the Ramsey County Society. The occasion was prompted by the retirement of Dr. Rothrock from active practice after some forty years devoted to his profession in Saint Paul.

The banquet was ably presided over by Dr. Arnold Schwyzer, and reminiscences and appreciation of the honor guest were expressed by Dr. O. W. Holcomb, president of the Ramsey County Society, Dr. John F. Fulton, Dr. J. T. Christison, and Dr. Henry Longstreet Taylor. Dr. J. C. Litzenberg, of Minneapolis, in behalf of the University, read a communication from the Board of Regents appointing Dr. Rothrock full Professor of Gynecology and Obstetrics at the University Medical School.

Dr. Rothrock responded with a brief sketch of the remarkable development of medical science which has taken place during his medical career.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

HOKAH WOMAN FOUND NOT GUILTY ON ABORTION CHARGE

State of Minnesota *vs.* Mae Jackson Mitchell

On Friday, December 11, 1931, after deliberating thirty-four hours, the jury in the District Court of Houston County returned a verdict of not guilty in the case of Mae Jackson Mitchell. The defendant was charged with having performed an abortion on a young married woman from La Crosse, Wisconsin, on or about May 16, 1931. The defendant is a woman about sixty years of age, residing in Houston County for the last twenty-five years. At the trial she testified that she was a practical nurse and a midwife. However, she holds no license to practice any form of healing in the State of Minnesota. Judge Karl Finkelnburg of Winona, Minnesota, who presided at the trial, informed the jury that he was very much disappointed with their verdict; that the evidence was amply conclusive to warrant finding the defendant guilty. At one time the jury stood nine for conviction to three for not guilty.

Judge Finkelnburg is to be commended for the public expression of the Court's opinion in this matter. The case was well and ably tried by Mr. W. E. Flynn, County Attorney of Houston County, Minnesota. Mr. Flynn and Sheriff Arthur C. Brown both are deserving of special thanks for the sincerity of their efforts in the preparation and trial of this case.

The State Board of Medical Examiners are determined to remedy a very bad situation that has existed in Houston County for some time and will take such steps in the future that conditions warrant irrespective of the outcome of this case.

UNLICENSED "SPECIALIST" DECIDES TO LEAVE STATE

"Dr." A. L. Collen, who claims to be from Chicago, and who has been operating in Winona County for the past thirty days, has informed Mr. E. D. Libera, County Attorney of Winona County, that he prefers to leave rather than face a prosecution for violation of the Basic Science Law. Collen claims to be a Doctor of Chemistry. He has been calling on farmers and other people in the vicinity of Winona selling them various preparations for stomach ailments, rheumatism and the like. When first interviewed Collen was very indignant over his being refused permission to operate in this State, his claim being that he was selling a medicinal preparation and could not be prosecuted for doing so. The evidence obtained by the State Board of Medical Examiners indicates that Collen has been holding himself out as a "Doctor" and a "specialist" from Chicago, furnishing preparations for the alleged relief of various ailments.

The Medical Board will appreciate hearing from anyone who has information indicating that Collen is still operating in this State.

THE COST OF PROPRIETARY AND NON-PROPRIETARY DRUGS

A comparison of the prices of drugs sold respectively under protected and non-protected names shows that the cost of the former is far in excess of the price for which the latter are sold. A comparison of the wholesale price of proprietaries compared with the cost of the drugs sold under their non-proprietary name shows that the total cost of one ounce each of these under a protected name is $25.30 while the cost of an ounce each under an unprotected name is but $6.40. The cost of the proprietary name to the consumer is $18.90. (Jour. A. M. A., October 24, 1931, p. 1226.)

A FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

They are getting together at last,—the doctors and the legionnaires.

One of the most important events of the year, from the standpoint of physicians and, we think, from the standpoint of veterans, too, was the conference called for Thursday, November 19, in Indianapolis between the committee appointed by the National Commander of the American Legion and the Legislative Committee of the American Medical Association.

These two committees conferred on new plans for care of veterans' disabilities. This care, according to the medical association committee, could be extended more promptly, more efficiently, less expensively—and without any dangerous dislocation of our economic system—through the medium of local civilian physicians and local civilian hospitals.

Four of the eleven men who sat around the Indianapolis Conference table were from Minnesota. They were C. B. Wright, Chairman of the Legislative Committee of the American Medical Association; E. A. Meyerding, State Secretary and a member of the same committee; Mr. Paul Fesler, President of the American Hospital Association and Superintendent of the University Hospital; and Patt Cliff of Ortonville, member of the Executive Committee of the American Legion.

These important conferences will continue at intervals throughout the year. Something of consequence, both to veterans and the medical profession, should develop.

Chairmen of Committees of the State Association should function for the President of the State Association very much as the cabinet functions for the President of the United States. An opportunity for this close advisory relationship is provided in the monthly Committee Chairmen's luncheon. The last meeting held at the University of Minnesota was given over mainly to discussion of the proposed modification of legislation for disabled veterans—this being the most important public question before the medical profession today.

C. B. WRIGHT (at this meeting): "We are accused of selfishness because we are 'trying to divert money now spent for care of veterans in government hospitals into the pockets of private physicians.' I welcome this charge of selfishness. We are not selfish for ourselves but for our profession. We are fighting, indeed, for the very life of the private practice of medicine. Not for ourselves, but for the men who shall come after us."

E. A. MEYERDING: "We shall have our best effect—not by sensational statements for the newspapers—but by individual and collective contacts with the veterans themselves. When the veterans understand our proposal they favor it. We cannot do better at this stage than to talk it over with the American Legion."

MR. PAUL FESLER: "The American Hospital Association has very carefully gone into this matter. There are approximately 1,200,000 beds in the hospitals of the United States at the present time and about 200,000 of them are vacant. The hospital association is prepared now to offer to the government approximately 76,000 first class beds in fully accredited institutions for the use of veteran patients."

"It has always been my contention," writes a distinguished member of the Medical Advisory Council to the Veterans' Bureau, "that government should not build and operate hospitals except to build the necessary additional facilities around existing medical organizations. This, incidentally, is the plan finally adopted by the Canadian government."

The Public Health Committee of the Ramsey County Medical Society presented an extremely important report at the November 30 meeting of the society. Every medical man could have listened with profit.

Obviously this committee has done a tremendous amount of careful research on the subject. Besides conveying a great deal of information, the report was characterized by eminently acute and intelligent interpretations of the general public health situation and its relation to the medical profession of today.

We take this occasion to congratulate the Ramsey County Public Health Committee. Any other medical group that inveigled the committee into repeating the report might consider itself lucky.

Have you noted the attractive series of public health lectures sponsored on three Sunday afternoons between December and March, by the Cleveland Academy of Medicine?

This group is the second in a series on the general subject, "Life in a Strenuous Age." This season's lectures include: "What Science Knows About Cancer," by Elliott C. Cutler, M.D., Western Reserve University; "Why Think About Eating?" by Henry Gerstenberger, M.D., Western Reserve University; and "Fighting Death After Forty," by R. W. Scott, M.D., Western Reserve University and Chief of the Medical Division, City Hospital, Cleveland.

These lectures are made possible through a gift to the Health Education Foundation of the Academy.

The United States Public Health Service comes in for suspicion and distrust now and then on the part of the foes of State Medicine. The following excerpts from an official bulletin of the service prepared by A. J. McLaughlin, M.D., Medical Director of the service, are particularly impressive and important, therefore.

Every practising physician should read this pamphlet entitled "The Medical Profession and the Health Department." It can be had for five cents from the United States Government printing office at Washington, D. C.

> "We speak of the organized medical profession," says Dr. McLaughlin, in this pamphlet. "But its organization is little more than provision for periodic meetings for the reading and discussion of papers on scientific subjects. An exaggerated sense of ethics makes many physicians shrink from anything like business organization; yet organization on a business basis, provision for clinic facilities, regulation of fees on a sliding scale basis according to income are absolutely essential if State Medicine is to be prevented."
>
> Again, "I should like to see the medical profession solve its own problem in its own way without outside interference by governmental or any other agencies. Proper organization of county medical societies will make State Medicine impossible, enable the physician to retain his self-respect and preserve that priceless, intimate, confidential relation that should exist between physician and patient."

Could anything in the way of a warning be more direct and forthright? Could it come from a more responsible, a better informed, a more impressive source? Surely in America there is neither official pressure nor economic necessity for any such drastic dislocation as State Medicine. American medical reforms are, indeed, "up to" the County Medical Society.

A GOVERNOR LOOKS AT CHIROPRACTIC

Governor Buck of Delaware has returned to the legislature, without his approval, a bill to create a board of chiropractic examiners and to regulate the practice of chiropractic. His summarization of the reasons for his veto is so clear and terse that it should be read by the legislators and governors of every state that is threatened or already afflicted with this cult. His statement follows:

> The purpose of the act, as I understand it, is to legalize the practice of chiropractic in this state. Practitioners of this cult are not recognized now. Do they profess to be doctors in the same sense of the term as is commonly understood to apply to men and women of the medical profession? Insofar as I am able to determine, there is not a recognized medical school in the country that includes in its curriculum a course in chiropractic. This fact in itself seems singularly significant.
>
> Even to the lay mind the idea that all disease of whatever character is due to spinal displacements of a mild sort, and that cures of such ailments as tuberculosis, smallpox, diphtheria, scarlet fever and others can be effected by manipulation and fingering of the spine is preposterous.
>
> Before returning this bill to you I have satisfied myself that the training and education a chiropractor, or drugless healer, needs to practice his art does not fit him properly to advisedly treat the sick, inasmuch as he is not qualified to diagnose ailments nor recognize communicable diseases and to take measures to control them. He is, therefore, an opponent to the department of health.
>
> Wherefore, it seems to me it would be inconsistent for the legislature to appropriate, as it will do, money for the state board of health, which board is trying to eradicate communicable disease, and at the same time legalize the practice of a cult which does not believe in the germ theory of a disease but does teach and believe that such diseases as scarlet fever, etc., are due to a distracted vertebra and the method to prevent and cure such disease is to see that everybody has a normal spine.—*Journal A. M. A.*

FOODS AND FOOD ADVERTISING

Today, advertising of foods, separate from the package container, is not controlled by any food statutes, and indeed is quite free of any efficient control. The writer of advertising of food products, aside from such limited knowledge of foods and nutrition as he may possess, has only a versatile vocabulary and his conscience as guides in dramatizing the virtues of the products he proclaims to the public. Under these conditions, advertising for food products began to approach the tales of Hans Christian Andersen and the brothers Grimm. Into this mass of mingled truth and deception entered the Committee on Foods of the American Medical Association. It is not surprising that its initial steps should have been greeted with apprehension and bitter deprecation by some of the organs of the food industry, of business and of advertising. The Committee on Foods was established to protect the readers of the journals published by the American Medical Association against improper claims made for foods. If the medical profession required such protection, how much more was the protection necessary for the average layman, to whom the same claims were made as were made to physicians. Only those who have been actively associated with the Committee on Foods can realize the vast amount of good already accomplished. (Jour. A. M. A., October 3, 1931, p. 1004.)

MISCELLANEOUS

THE GENESIS OF SOCIAL INSURANCE

Edward H. Ochsner, M.D.
Chicago

(The following article is one of several which will appear simultaneously in other state journals dealing with various phases of Social Insurance. In view of the growth of the idea of governmental responsibility for the medical and economic care of its citizens, the subject is one of prime importance to the American public at large as well as to the medical profession.)

Social Insurance is the hybrid offspring of impracticable sentimentalism and political expediency. It is an epidemic disease first observed in Germany about fifty years ago which has gradually spread and infected a considerable number of the nations of the earth and now has arrived at our very doors. Unless we succeed in establishing a rigorous quarantine of enlightened public opinion, it will surely gain a foothold in this country in the not distant future.

Social Insurance consists of the following subdivisions or parts: Compulsory health insurance, old age pensions, widows' and orphans' pensions, and unemployment pensions or doles. In none of the countries were 'they all adopted at the same time. Germany adopted compulsory health insurance in 1883, and all of the other forms since that time. Austria adopted compulsory health insurance in 1888; Hunary, in 1891. England adopted old age pensions first and compulsory health insurance in 1911, and the others subsequently. In this country some of the states have adopted old age pensions and some widows' and orphans' pensions, but so far none have adopted compulsory health insurance, for which negative blessing let us raise our voices in thanksgiving.

When the scientific physician is confronted with the problems presented by a new patient, he meets the situation in the following manner: he obtains a complete family and personal history in order to ascertain if possible the causes which have brought about the condition; by his physical examination and laboratory investigations he finds out what variations from the normal have taken place; after all this he is in a position to advise and institute the proper treatment. Let us follow the same course in the study of this problem.

During the late seventies a number of German parlor socialists conceived the idea that the state make itself responsible for the medical care of its workers. The sentiment in favor of compulsory health insurance grew rapidly among the workers, and Bismarck, although expressing serious doubts as to the soundness of such a measure, yet feeling that something had to be done in order to appease the clamor of the proletariat and the alarming growth of socialism, adopted social insurance as a government measure, had a bill drafted and enacted into law.

In England, National Insurance, as it is called there, had a slightly different setting but substantially the same background. In 1910, David Lloyd George in order to strengthen himself politically decided the time for such legislation was opportune. Not being able to speak German, he gathered about himself several interpreters, hied himself to Germany and after interviewing the well paid heads of the German system, and after having been wined and dined and lionized for two weeks or so, he returned to England very enthusiastic about the whole project, had a law drafted, and later secured its passage. In the recent parliamentary election the Liberty party, of which Lloyd George has been the head for many years, elected just four members to Parliament or less than one per cent of the whole number. So while Lloyd George may have saved his political skin by National Insurance in 1911, he certainly lost his hide by it in 1931.

Practically every reform movement attracts to itself a considerable number of well meaning, emotionally impressionable, impractical, irresponsible, very vociferous individuals, and very often a group, usually the very ones who manage the propaganda and who hope to gain some pecuniary benefit from it. Social Insurance is no exception to this general rule.

Some of the common characteristics of reformers is that they want a new law passed for every human ill, and when the law is enacted they either sit back waiting for the millennium to arrive or they rush off looking for new evils to correct by new laws, forgetting to see to it that the law just passed is being properly enforced, and forgetting at all times that all laws must depend for their enforcement, not upon supermen, but upon men often of less than average intelligence and integrity, upon politicians and their henchmen, who are quick to see how these usually unsound and loosely drawn laws can be converted to their own advantage.

(The foregoing is what is actually happening in some of the countries where such laws are in operation, as future installments will show.)

LISTERINE, AN EXAMPLE OF BOTTLED PSYCHOTHERAPY

The odor and taste of thymol with a little of this and that. The formula given on the carton, "Thyme, eucalyptus, baptesia, gaultheria and mentha, of each one part, boric and benzoic acids, twenty-nine parts, ethyl alcohol, two hundred and fifty parts, water to make one thousand parts. Lambert Pharmacal Company," is merely "a formula." The A. M. A. Laboratory found that the following gives a solution practically identical (chemically and bacteriologically) with Listerine: Boric acid 23.4 Gm., benzoic acid 0.4 Gm., alcohol (94%) 280.0 c.c., menthol 0.375 Gm., thymol 0.75 Gm., eucalyptol 0.8 c.c., methyl salicylate 0.1 c.c., baptesia (wild indigo) fluidextract N. F. 10.0 c.c., water to make 1000.0 c.c. What progressive physician would attempt to write such a polypharmaceutical prescription! (Jour. A. M. A., November 14, 1931, p. 1466.)

OBITUARY

Dr. Frank Lee Puffer

1853-1931

The death of Dr. F. L. Puffer of Bird Island occurred in May, 1931. Born in 1853 and receiving his degree from New York Medical College in 1877, he began practice in Beaver Falls in 1878. He was preceded by just two other doctors in Renville County, namey, Dr. H. Schoregge, who came to Henryville in 1870 and Dr. C. S. Knapp who began practice in Cairo in 1871.

To quote from an editorial which appeared in the Olivia Times:

"Dr. Puffer was a true physician, with a proper conception and estimation of the real character of his profession. His doctrine was one of helpfulness to others, and his practice was to give freely of his service to those in need of it regardless of the consequences to him. In speaking at a Kiwanis club luncheon in Olivia about a year ago, Dr. Puffer related some of his most thrilling experiences in early days in this county. On the evening of October 15, 1880, he was called to see a sick patient seventeen miles from Bird Island. After a long ride over the bleak prairie he reached his destination, but shortly afterwards a storm set in, blocking all roads and making travel uncertain and almost impossible. He stayed several days at his patient's home, then started to shovel his way back to town. On the return he made a detour to see another patient, shoveling his way to this home, and from there to Bird Island, and finally reached home on October 22, just one week from the day he started out on the call. This was only one of the many such experiences he related, and during his brief talk his audience had a picture of devotion to duty brought before their minds, of a lone figure making its way across the bleak prairies of Renville county in 1880, pressing on and on, with great bodily suffering and discomfort, but with a devotion to duty that challenged the admiration of all his hearers.

"The passing of those good, old pioneers gives occasion for profound sadness and regret. They were so human, so self-sacrificing and their lives so in keeping with the best aspirations of the human heart, that we feel their loss most keenly. On the other hand, the opportunity for service came to them as it comes nowadays to very few, and in passing they leave to us a record of service, a lesson of devotion to duty, worthy of the pioneers and of lasting benefit to future generations."

Hugh Spaulding Willson

1877-1931

Word has been received of the death in La Jolla, Calif., of Dr. Hugh Spaulding Willson, fifty-five years old, who practiced medicine in Minneapolis from 1913 to 1926 as a member of the firm of Willson, Cabot and Wohlrabe.

Dr. Willson was born in North Dakota in 1877. He was graduated from the school of medicine of the University of Minnesota in 1904. In the World War he served overseas as commanding officer of base hospital number 70. Following his graduation from the University of Minnesota he was connected with the staff of the Mayo Clinic in Rochester for several years. He specialized in internal medicine.

Dr. Willson is survived by his wife, Mary, and his father, who lives in North Dakota.

H. J. Rowe

1848-1931

Dr. H. J. Rowe died Friday, November 20, 1931, at his home in Minneapolis.

Dr. Rowe had been a resident of Minneapolis four years. For many years he was secretary of the North Dakota State Medical Association, and was a grand officer of the North Dakota Odd Fellows and prominent in Masonic work.

Surviving are his wife and two sons, Dr. Paul Rowe of Minot, N. D., and Dr. Arthur Rowe of New York.

Robert H. Harrison

1862-1931

Dr. Robert H. Harrison, Saint Paul, in charge of the government serum plant at South Saint Paul, and for thirty years a resident of Saint Paul, died at his home Sunday, December 13, 1931, after ten weeks' illness.

Dr. Harrison, both a doctor of medicine and a veterinary surgeon, helped to found the veterinary department at Harvard as a young man. Born in New York, March 9, 1862, he attended New York Medical College, and Harvard. In 1898 he entered the government service and since had been stationed at Milwaukee, Eau Claire and South Saint Paul.

His widow and a son, George, of St. Paul, and two sisters, Mrs. Albertine J. Williams of Philadelphia, and Miss Lucie R. Harrison, living in England, survive.

THEELIN

And the Technic of Introduction of New Drugs.—For many years the Council on Pharmacy and Chemistry has fostered certain broad principles governing the introduction of drugs. Often after a drug has shown promise of considerable merit it has been introduced through wrong channels or by misdirected publicity. To safeguard the scientific integrity and academic interests of the Doisy discovery of the crystalline sex hormone, the St. Louis University School of Medicine devised a plan on the basis of precedent which may serve as a guide to others in the introduction of a new medicament. Irrespective of whether or not theelin is found valuable for medical practice, Dr. Doisy and St. Louis University are to be congratulated on taking such precautionary steps, thus placing the introduction and control of the remedy on a high plane. (Jour. A. M. A., November 21, 1931, p. 1541.)

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The programs for the month of January will be as follows:

January 6—Personal Hygiene—Physical Activity.
January 13—Causes of Bad Breath.
January 20—Three Score and Ten Approaches.
January 27—Warning Signs of Cancer.

STATE CONFERENCE OF SECRETARIES

Three major discussions will occupy convening secretaries and a large number of out-of-state visitors at the annual Secretaries Conference of the Minnesota State Medical Association to be held Saturday, January 23, at the Saint Paul Hotel.

A symposium on the general subject, "Medical Care of the Poor," will occupy the major part of the morning session. The luncheon meeting will be devoted to a series of talks on the subject, veterans' legislation and contemplated reforms. A symposium on the periodic medical examination will follow in the afternoon.

Mr. H. Van Y. Caldwell, Secretary of the Cleveland Academy of Medicine, is among the important out-of-state speakers who are coming to St. Paul especially to address this conference. Many others who will attend the Northwest Regional Conference on the Sunday following the Secretaries' Conference will also come in time to speak at both meetings. Among them are Mr. Vernon D. Blank, Des Moines, General Manager of the Iowa State Medical Society; Mr. Theodore Wiprud, Milwaukee, Executive Secretary of the Medical Society of the County of Milwaukee; H. M. Camp, M.D., Executive Secretary of the Illinois State Medical Society; Mr. T. A. Hendricks, Executive Secretary of the Indiana State Medical Society; Dr. Otto Fcidler, President of the Wisconsin State Medical Association; Mr. George B. Larsen, Secretary of the Polk County Medical Society, Frederic, Wisconsin.

REGIONAL CONFERENCE

The regional conference composed of officers of state medical societies of the Northwest resumed its annual informal conferences last year, after a lapse of several years. Its 1932 program for discussion includes Social Medicine, Contract Practice, The Shoulders Resolution Auxiliary Committee, Lay Education, State Medical Journals, and the Periodic Medical Examination. The states participating in this conference include Minnesota, Wisconsin, Iowa, North and South Dakota, Nebraska and Montana.

FRACTURE SYMPOSIUM

On February 3 and 4, 1932, there will occur in Minneapolis a discussion of the modern treatment of fractures. This is being conducted under the joint auspices of the Minneapolis Regional Sub-Committee of the General Fractures of the American College of Surgeons and the Minneapolis Surgical Society.

On Wednesday evening, February 3, 8 o'clock in the Auditorium of the Hennepin County Medical Society a symposium on the treatment of fractures will be held.

The program on Thursday, February 4, will be entirely under the direction of the Minneapolis Surgical Society in connection with its annual formal meeting. Dr. Kellogg Speed of Chicago, an outstanding authority on the subject of fractures, will be the guest speaker. At 10 o'clock, Thursday morning, Dr. Speed will conduct a fracture clinic with demonstration of cases at the Minneapolis General Hospital. At 3 P. M. he will lecture to the students of the medical school, and following the annual formal banquet of the society in the Nicollet Hotel at 6 P. M. he will deliver an address before the society.

All members of the profession in good standing are invited to attend these meetings, including the banquet.

Reservations for the banquet must be made with the secretary, H. O. McPheeters, At. 5579, before Wednesday noon, February 3, 1932. Banquet tickets are $2.00.

STATE MEDICAL AND HOSPITALS ASSOCIATIONS

For the first time in their history, the Minnesota State Medical Association and the Minnesota State Hospital Association will hold their annual meetings at the same time and under the same roof this year.

The sessions will begin May 23 at the new St. Paul Auditorium and continue through May 25.

This much was definitely decided upon at the first meeting of the Committee on Scientific Assembly December 5, to which officials of the state hospital body were invited.

Ample lecture and clinic rooms for both organizations are available in the new building, now close to completion. Exhibits for both organizations will be assembled in the large new exhibit room of the building. One large general meeting is being arranged tentatively for Monday night, May 23, which will unite both organizations and the Women's Auxiliary to the Medical body. The subject on this occasion will probably be "Veterans Legislation."

Another new feature of the tentative meeting schedule should be of particular interest to Twin City physicians. For the convenience of the latter, all distinguished out-of-state speakers, of whom four or five are now under discussion, will be booked to talk at noonday sessions.

Arrangement of the scientific program by small sections instead of large general sessions is also under consideration by the committee. If present plans materialize there will be fifteen different sessions in the three day program. Only a few of the these, including the noonday sessions, will be general meetings.

The afternoon of the 25th will be devoted exclusively to clinics if present plans of the committee are carried out. If possible, these clinics will be held at the Auditorium itself, where ample room is available, thus avoiding the inconvenience of moving the meeting to the University or the hospitals.

Final selection of speakers and subjects will be determined largely by responses to the questionnaire already sent out to all members of the association.

CHAIRMEN OF COMMITTEES MEETING

A complete report of the results accomplished in the recent meeting of committees from the American Medical Association and the American Legion in Indianapolis chiefly occupied the chairmen of committees of the State Association at their last regular meeting, held at the Minnesota Union at the University, Monday, November 28.

C. B. Wright of Minneapolis, chairman of the Legislative Committee of the American Medical Association, and E. A. Meyerding, St. Paul, Executive Secretary and member of the Auxiliary Committee on Veterans' Affairs, both of whom attended the Indianapolis meeting, spoke.

Mr. Paul Fesler, superintendent of the University Hospital and President of the American Hospital Association, and A. Calvin, Superintendent of Midway Hospital in Saint Paul, were present by invitation to explain the hospital men's attitude on the subject.

A brief report by J. A. Watson, Minneapolis, chairman of the Committee to Coöperate with the Minnesota Editorial Association, on the last meeting of his committee with the editors concluded the program, which ended as agreed upon at 2:00 o'clock promptly.

The next chairmen's meeting was set to coincide with the Secretaries' Conference, January 23, in Saint Paul.

CAMP RELEASE DISTRICT SOCIETY

The annual meeting of the Camp Release District Medical Society was held at Granite Falls, Minnesota, Monday afternoon and evening, November 30, 1931.

Following the business session in the afternoon a Skin Clinic was held under the direction of Dr. W. H. Goeckerman of the Mayo Clinic. Dr. Goeckerman addressed the members on the subject "Eczema and Urticaria."

At 6:30 o'clock a joint dinner with the District Auxiliary was held at the Riverside Hotel. Following the dinner short addresses were given by Dr. L. Sogge, president of the State Medical Association, Windom, Dr. H. M. Workman, District Councilor, Tracy, Minnesota, and Mrs. James Blake, president of the State Auxiliary, Hopkins.

The evening's program consisted of two addresses. Dr. Lewis Jordan, Granite Falls, spoke on "Tuberculosis" with demonstrations of the Mantoux test. Dr. Willard White of Minneapolis spoke on "Some Problems in Treatment of Fractures."

The following officers were elected for the ensuing year: F. W. Penhall, Morton, president; G. H. Mesker, Olivia, vice-president; J. Dordal, Sacred Heart, secretary-treasurer; L. J. Holmberg, Canby, delegate to annual meeting, with M. A. Burns of Milan as alternate.

RICE COUNTY SOCIETY

The annual meeting of the Rice County Medical Society was held in the Faribault Clinic Rooms on Tuesday, November 10, 1931, at 7:45 p. m.

Dr. W. E. Wilson, Northfield, read a paper entitled "A Review of a Poliomyelitis Epidemic." Dr. E. C. Rosenow, Rochester, spoke on "Bacteriologic and Immunologic Studies of Poliomyelitis."

Election of officers for 1932 resulted as follows: President, Dr. J. M. Murdoch, Faribault; vice president, Dr. W. E. Wilson, Northfield; second vice president, Dr. Edmund Backe, Kenyon; secretary-treasurer, Dr. C. J. Plonske, Faribault; delegate to State Meeting, Dr. A. M. Hanson, Faribault; Censors, Dr. F. M. Babcock, Northfield, Drs. M. L. Mayland and S. B. Hessaly, Faribault; Publicity Committee, Drs. F. U. Davis and P. A. Smith, Faribault; Dr. O. P. Thorson, Northfield.

WRIGHT COUNTY SOCIETY

The annual meeting of the Wright County Medical Society was held at Buffalo, Minn., Tuesday, October 6, 1931.

Minutes of the Delano meeting were read and accepted.

A paper on "Diabetes Mellitus" was read by Dr. C. L. Roholt. Dr. E. Klaveness read a paper on "Medical Ethics." Dr. Klaveness' ideas were clearly set forth both from the standpoint of personal opinion and from experience. He is to be congratulated on his courageous expression on such a delicate and unpleasant subject when handled locally.

Election of officers for 1932 resulted as follows: Dr. F. Ellison, Monticello, president; C. L. Roholt, Waverly, vice president; J. J. Catlin, Buffalo, secretary; Oscar Freed, Cokato, delegate to State Meeting; E. Klaveness, Saint Paul, alternate; George Nonis, Annadale, censor for three years.

The Ladies' Auxiliary were entertained by Mrs. J. J. Catlin.

Drs. C. B. Wright and N. Pearce, of Minneapolis, gave a talk on the Various Aspects of Medical Economics, a very interesting and a most timely subject worthy of serious consideration.

C. L. Roholt, *Secretary.*

WOMEN'S AUXILIARY
Minnesota State Medical Association

CAMP RELEASE AUXILIARY

The annual business meeting and election of officers of the Women's Auxiliary to Camp Release Medical Society was held at Granite Falls, Monday afternoon, November 30. Mrs. J. S. Kilbride, retiring president, presided at the session. New officers elected are: President, Mrs. R. C. Adams, Bird Island; first vice president, Mrs. J. Dordal, Sacred Heart; second vice president, Mrs. M. A. Burns, Milan; secretary, Mrs. G. H. Mesker, Olivia; treasurer, Mrs. M. S. Nelson, Granite Falls.

Mrs. James Blake, of Hopkins, state president, gave a splendid address on the work of the Auxiliary at the afternoon session.

At 6:30 a joint dinner with the members of the medical society was given at the Keegan hotel. The dinner program included talks by Dr. L. Sogge, Windom, state president of the medical society; Dr. H. M. Workman, Tracy, district councilor; and Mrs. James Blake, state president. A rising vote of thanks was given Mrs. Blake for her inspirational address.

HENNEPIN COUNTY AUXILIARY

The Christmas party of the Woman's Auxiliary to the Hennepin County Medical Society was held on Wednesday, December 16, in the room of the Hennepin County Medical Society. "The Lonesome Christmas Tree" was the subject of a reading by Mrs. E. Z. Wanous. The program, which was arranged by Mrs. C. E. Proshek, included the singing of Christmas carols by a group of Slavic children and Christmas songs by the children from St. Mary's Russian church.

MOWER COUNTY AUXILIARY

The auxiliary of the Mower County Medical Association held an open session Monday, November 30, at the Y. W. C. A. rooms. About fifty women were present. Besides the members who are the wives of Mower County doctors, the presidents of the Parent-Teacher Association were present.

The president, Mrs. A. W. Allen, presided. In an informal way, she told how the organization was formed last April with the following officers, besides herself: Vice president, Mrs. M. W. Morse of Le Roy; secretary, Mrs. P. A. Lommen; and treasurer, Mrs. G. E. Hertel. Five meetings had been held. The work taken up was sewing for the local hospital.

Mrs. Allen then turned the program over to Mrs. C. C. Allen, who for some time has been especially interested in health work. Aside from musical numbers, the program consisted of reports from the Regional Conference of Health and Social Work which was held at Kasson, November 6. Mesdames A. W. Allen, C. C. Allen, C. L. Sheedy and B. J. Cronwell, were present at that meeting.

RAMSEY COUNTY AUXILIARY

The auxiliary to Ramsey County Medical Society met Monday, December 7. The auxiliary had offered a silver cup to the Saint Paul High School student submitting the best essay on the Christmas seal week.

STATE AUXILIARY

Seventy-five essays on "Today's Fight Against Tuberculosis" were received and the ten best were broadcast over Radio Station WCCO. The woman's auxiliary to the State Medical Society had donated two cups to be given to the two best essayists.

PROCEEDINGS OF THE MINNEAPOLIS SURGICAL SOCIETY

Meeting of November 5, 1931

The regular monthly meeting of the Minneapolis Surgical Society was held in the Lounge on the 20th floor of the Medical Arts Building on Thursday evening, November 5, 1931.

The meeting was called to order at 8 p. m. by the President, Dr. J. Frank Corbett. There were 27 members and 5 visitors present.

The following scientific program was presented.

Dr. A. F. Bratrud reported a case of Lipoma at the Ileocecal Valve Causing Intestinal Obstruction, as follows:

The case presented this evening is that of a woman 67 years of age who was first seen and examined on April 6, 1931. She had been in very good health up to about five years ago, at which time she had some form of operation for removal of a brain cyst. She had pneumonia at 45 years of age and normal menopause at 48 years of age. The family history was negative.

Her present complaint dated back to about October, 1930, at which time she first noticed sharp cramps in the right side of the abdomen, with radiation of pain across the abdomen. She states that it felt as if there was a growth in the abdomen. There had been a gradually increasing weakness, with 20 pounds loss of weight since October 1, 1930. She complained of difficulty in keeping the bowels open. There would be a day or two, at intervals, when the bowels would be rather loose. She has had distention of the abdomen with belching of gas, but no nausea or vomiting. There had been palpitation of the heart at times, and during the previous week she had had dizziness. The dizziness occurred either while lying down or while up and around.

Examination showed a fairly well-nourished and fairy well-developed woman about 67 or 68 years of age. Blood pressure 140/68; temperature 98°; pulse 74. The skin appears as though the patient had lost some weight. There is an area about 1.5 inches in diameter in the mid-parietal region of the cranium where bone has been removed. She had had an occasional cough which is noticeable when she is lying in bed and which seems to cause some distress. The mouth, ears, nose and neck are normal. There is no adenopathy. The heart is enlarged to the left to the anterior axillary line. There is a systolic murmur heard at the apex ending at the second sound. The breath sounds of the right chest are normal. There is bronchovesicular breathing in the left chest. Slight distention of the abdomen is noticed. There is tenderness and spasm in the right lower quadrant of the abdomen with the suggestion of a mass close to the crest of the ileum. This is not movable. Percussion at the costal margin is negative. Rovsing's sign is negative. Pelvic examination is negative. The reflexes are normal. The urine shows a specific gravity of 1.021, with a trace of albumin, no sugar, and numerous pus cells. The phenolsulphonephthalein test showed a return of 32.5 per cent in two hours. The blood chemistry showed sugar 0.108; urea nitrogen 19.6 mgms. White blood count was 7,200; differential—pmns. 74, lymphos. 21, eos. 4. The hemoglobin on April 8, 1931, was 92 per cent; on May 11, 1931, was 77 per cent.

Electrocardiogram—P-wave broad and flat; R-wave slurred, descent gradual. The tracing does not look exactly normal, but there are no definite changes that would contraindicate operation.

A series of plates and fluoroscopic examination made immediately after a barium meal showed the stomach normal in size, shape and position. There is no deformity of the walls of the stomach and the cap is clean-cut and not deformed. Examination at 6 hours shows the entire meal in the lower ileum.

A barium enema was administered under fluoroscopic control and plates were made. These show a moderate spasm involving the entire colon. There is a localized filling defect of the lower portion of the cecum with a moderate degree of spasm involving the ascending colon. Conclusion: Normal stomach and cap; I believe the findings in the cecum represent a carcinoma.

On April 13, 1931, under spinal anesthesia, a right rectus incision was made in the lower abdomen. There was an indurated nodular mass involving the head of the cecum and about the ileocecal valve, the mass being about the size of a fist. There was an indurated area retrocecal to the cecum ascending up about 4 inches. The cecum was adherent to the right broad ligament. The pelvis was negative; liver negative. A resection and aseptic anastomosis, end-to-side, of the terminal ileum with the transverse colon, was performed. Inversion of the terminal portion of the ileum was performed, leaving the stump of the distal ileum with the cecum still within the abdominal cavity. Closure was made in layers without drainage. The postoperative course was uneventful.

On April 28, 1931, under spinal anesthesia, the old scar was excised, extending the right rectus incision to above the umbilicus. The mass at the head of the cecum was much smaller, being about the size of a medium sized orange. There were no glands posterior to the cecum. There were very few adhesions following the operation two weeks previously. Resection of the cecum, terminal ileum and including the ascending colon and hepatic flexure of the colon was performed. The stump of the transverse colon was inverted and final closure was made with linen with peritonealization of all surfaces. The closure was made in layers without drainage.

Report on specimen removed: Cecum widely resected. The walls are very thick with a tissue closely resembling fat. Walls are an inch thick in places. The lumen of the intestine is small and the mucous membrane fairly regular and smooth. The tissue causing the thickening and obstruction originates from the outer coats of the intestine. There is narrowing and obstruction present.

Section: Great deal of fatty and fibrous tissue. Considerable round cell infiltration of the muscle layers of the intestine. The glands appear normal in size and shape. There is a great number of eosinophiles between the columns of the glands. There is no evidence of malignancy.

The pre-operative treatment in this case consisted principally in high caloric diet with digitalization and sedatives. Ergot was given pre- as well as post-operatively. The post-operative course was uneventful. She was discharged from the hospital on May 17, 1931, with the wound well healed and feeling well. She was last seen and examined on September 5, 1931, feeling extremely well and back to normal weight. At that time she was eating practically all foods and having practically no intestinal disturbance at all.

Comments: It was impossible to determine at the time of operation whether this was a benign or a malignant condition from the appearance of the tumor. On account of the rarity of this type of tumor, it was not even suspected. The origin of this tumor, according to Ewing, is different from that of those reported. This growth arose apparently from the outer coat of the intestine, whereas they usually arise from the submucosa or from appendices epiploicæ of the colon. It is believed that this type of tumor causes more pain or cramps than a malignant condition on account of the location of the tumor. Even with the high hemoglobin, the true nature of the tumor was not suspected.

DISCUSSION

Dr. E. T. Bell (by invitation) stated that he had seen several benign tumors in that location but had never come in contact with a lipoma at that place. The benign tumors of the intestinal tract are rather rare compared with the malignant ones, the more common ones being myomata and benign glandular polyps. But the lipoma is a distinctly rare form of tumor in the intestinal tract. He said that nothing in particular is known about the cause of these tumors.

Dr. J. F. Corbett asked as to the size of this tumor and also whether it was annular.

Dr. Bratrud said that originally the tumor was about the size of a man's fist, but at the time of the second operation it was only about one-half that size. The ileocecal valve even at the second operation seemed to be practically closed.

Dr. McPheeters asked if it felt like carcinoma.

Dr. Bratrud replied that it was impossible to determine what type of tumor it was from the gross appearance. He did not think that it really felt as firm and nodular as a carcinoma in this location should feel. The one thing that made him doubtful about this being a carcinoma was the fact that there were no glands retrocecally.

Dr. Willard C. Peterson read his Inaugural Thesis on "Chronic Recurrent Appendicitis."

ABSTRACT

The object of the study is to determine whether there are any characteristic structural changes in the appendix in the so-called chronic appendicitis. The material consists of 100 cases of chronic appendicitis which have been thoroughly studied clinically. Each appendix was sectioned in three places. The author gave a review of the clinical phenomena, the differential diagnosis, pathology and a review of the literature. The classification of the lesions found in this series he made as follows:

1. Clear-cut type of chronic inflammation.
2. Chronic periappendicitis.
3. Patent appendix.
4. Obliterative appendix.
5. Carcinoma, cysts, anomalies, and tuberculosis.
6. Normal.

The author also gave a review of the treatment and post-operative results.

Dr. Kenneth Bulkley gave a lantern slide talk showing the lesions caused in the appendix by parasites—oxyuris vermicularis and trichocephalis dispar—as a possible etiologic factor in appendicitis.

Dr. Bulkley thought that possibly it was unfortunate both for surgeons and for the public that there is so much appendicitis; its very frequency tended to make both groups of individuals belittle its importance. He felt that Dr. Peterson's paper was worth while inasmuch as any study which contributed toward our knowledge of the etiology of this disease was of value. In the last analysis, no one knows anything in regard to the etiology of appendicitis or its prevention except that it seems to be an established fact that a break in the mucosa is probably essential for the development of appendicitis. The only absolute prevention of appendicitis is to remove the normal appendix prior to the onset either of inflammation in it or prior to the onset of symptoms from it. In this connection Dr. Bulkley cited an experience which he had some eighteen years ago in which he assisted a prominent New York surgeon, now dead, in removing four normal appendices from his four normal children who never had had symptoms of appendicitis, these operations being done because of an unfortunate experience with his fifth child who had developed a gangrenous appendix during his absence.

In connection with the etiology of appendicitis, Dr. Bulkley wished to call the attention of the members to the role possibly played by parasites in causing not only definite breaks in the mucosa of the appendix but definite lesions in the wall of the appendix. The parasites most commony at fault were the oxyuris vermicularis or pin-worm or seat-worm and the trichocephalis-dispar or whip-worm. Dr. Bulkley then demonstrated by means of some twenty lantern pictures, a series of microscopic slides showing the lesions caused by both of these parasites from their early penetration through the columnar epithelioma to their eventual death and hyalinization through fibrous encapsulation by the host. Dr. Bulkley called attention to the fact that this subject was largely overlooked chiefly because of the lack of proper technic in the search for these parasites. He called attention to the fact that if their percentage incidence was to be correctly estimated, not only was it necessary to examine microscopically the contents of the appendix but that it often was necessary to make large numbers of serial sections of the appendix walls; that it was only by so doing that he and Dr. R. L. Cecil, with whom this work was originally done some eighteen years ago, had been able to find the lesions demonstrated to the Society tonight.

DISCUSSION (on thesis and lantern slides)

Dr. E. T. Bell (by invitation) stated that this form of appendicitis is the only kind which pathologists recognize as chronic appendicitis, and it is chronic in the sense of recurrent acute attacks. As Dr. Peterson pointed out, this is clinically the same as ordinary appendicitis except that the attack is more mild. But there are all degrees of intensity of attacks. Some of these patients have had eight attacks over a period of years. The intense symptoms last several days, then soreness and tenderness continue for possibly several weeks. So far as Dr. Bell had noticed, these are the only kind of attacks these patients have—fairly mild attacks—and he had never seen any which went over into the gangrenous form. He stated that there is nothing known to pathologists as chronic appendicitis in the sense that syphilis or tuberculosis is chronic, but these are just a series of mild acute attacks.

When one operates, the appendix looks normal unless microscopic sections are cut, and for this reason sometimes the surgeon is much embarrassed because he may think he has operated on a normal appendix. But a microscopic section brings out quite clearly an inflammation in the serous layer of the appendix. The typical acute appendicitis starts from the mucosa; then the inflammation spreads out to the serosa. If one could get these cases in the first few hours of the attack it would be possible to find the primary mucosal lesion; but after a day or so it has spread to the whole appendix, the extension to the muscularis and mucosa being secondary. The inflammation is characterized by lymphocytes. It is not an acute process in which one finds polymorphonuclears. It is only on microscopic section that this is shown. In a great many of the cases in which the surgeon may think the appendix is normal, it really is not. Dr. Bell said it is not known whether the appendix is responsible for the symptoms in cases in which it is normal microscopically.

Then there is the obliterated appendix which is found in some cases, in which there is no lumen in the appendix. He could not feel that that type of appendix could possibly cause symptoms. This latter type of appendix increases in frequency with age; the older the patient is, the more likely is he to have an obliterated appendix.

Then there is the question of fecaliths, which may cause cramps. But a great many of these fecaliths are found in the appendix postmortem in patients who have never had symptoms.

Another form is the type with adhesions about the appendix. Young children have practically no adhesions at this point, but in each decade more and more of them are found, and they are seen in more than half the middle-aged. These are often seen postmortem, and it is difficult to believe that these adhesions are the cause of the symptoms. They might be, but evidence is against it.

Then there is a benign tumor of the appendix which is commonly called carcinoma, but since it is not malignant a better term is "carcinoid." Microscopically it looks malignant but it isn't. It forms a hard button at the end of the appendix but never gets outside the organ. It causes inflammation.

Dr. Bell stated that this chronic appendicitis is a well-defined type of appendicitis in which the appendix looks normal but on microscopic sections one finds inflammation in the serosa.

He was also of the opinion that people who have indefinite abdominal complaints very seldom have appendicitis and the follow-up usually shows they have some other disease. He had seen several cases of renal stone giving the same symptoms, and to cover all these up with the name of "chronic appendicitis" is not helping the surgeon. Dr. Bell said he did not want the members to think he was taking the attitude of criticizing the surgeons for taking out an appendix when they have a clinical picture of appendicitis, for if the surgeon is too conservative he may lose a patient who has a gangrenous appendix. He did want to say that when an appendix is removed and found to be normal histologically, the patient should be thoroughly studied to see if a similar error might be avoided in the future.

He also called attention to the term, very common in French literature, of "perityphlitis," in which there is inflammation around the cecum and appendix, but he had not seen infections of that type. While he had seen quite a lot of inflammation which had spread around the cecum it seemed to be definitely traceable to the appendix.

Then of course there are the parasites in the appendix which may be the cause of appendicitis. The most common of these are the pin worms and thread worms.

Dr. Bell stated that these were very amazing pictures which Dr. Bulkley has shown and while he had had a general idea that worms were the cause of some appendicitis he had seen only two or three such instances. However, he had not studied appendices in serial sections or he might have seen more of them. He said it was difficult for him to believe that they are as common in this section of the country as in the material which Dr. Bulkley has shown tonight. Dr. Bell said he usually chose three levels in the appendix for sections. He believed the basis of appendicitis is well established; that anything which denudes the mucosa is liable to cause infection, so it is easy to see how these worms can give rise to appendicitis. He had seen appendices postmortem with worms in them that had not caused symptoms. Pathologists in general have not felt that parasites are the cause of appendicitis. They do not know what starts the inflammation but the bacteria of the intestinal tract are about the only bacteria that are found in the pus. Something happens that opens a passage into the mucosa and anything that can do that can cause appendicitis, but no one has offered any explanation as to just what the thing is that starts it. Efforts have been made by some to connect it with sore throat, gallbladder, etc., but so far none of that work is convincing. Dr. Bell stated that it might well be that these parasites which Dr. Bulkley has shown play a much more important role than has yet been credited to them.

Dr. Bulkley added that there is another phase of the subject of parasitic infestation of the appendix which although it does not bear on the etiology of appendicitis does nevertheless possibly throw some light as to why clinically oxyuris and trichocephalis infestation of the intestinal tract is so difficult to cure. In practically all of the examinations made in connection with the work just mentioned there was found in the lumen of the appendix both sexes of the infesting parasite. As far as is known, neither cathartics, anthelmintics nor rectal medication have any effect toward emptying or washing out the inside of the appendix. It is not improbable that these parasites breed within the appendix and that it is for this reason that the medical treatment designed to eliminate them is so often a failure. Dr. Bulkley cited an instance of a woman in the fifties who since childhood had been known to have infestation with the oxyuris and who never at any time had had symptoms referable to her appendix. This patient because of distressing itching about the anus had repeatedly throughout her life made serious attempts under medical supervision to rid herself of these worms but without success. Dr. Bulkley removed this woman's appendix with the sole object of clearing up this woman's infestation. The appendix itself was normal but was found to contain parasites of both sexes. This woman received no further treatment whatsoever designed to eliminate her parasites; nevertheless her anal itching ceased and repeated stool examinations over a period of two years failed to again show parasites or their ova. This case was previously reported in the Annals of Surgery in 1912.

Dr. J. F. Corbett felt there were many phases of this discussion. He said he realized how serious it sometimes is to slip up on a diagnosis of appendicitis, and recalled a colleague who had what seemed like a very mild attack of appendicitis, although Dr. Corbett himself did not feel that it was. The next attack was a fulminating one and the man almost died. He felt that surgeons should not lean too far back in their diagnoses. Some points which Dr. Bell mentioned, *i.e.*, the danger of lawsuits and the unscrupulous surgeons operating unnecessarily, are two things which should be kept in mind. Dr. Corbett asked the members for a full discussion of this interesting paper and Dr. Bulkley's report.

Dr. F. A. Olson said he wished to congratulate Dr. Peterson on the completion and presentation of this very fine piece of work. He also wished to congratulate Dr. Bell, who had suggested and stimulated the research.

Dr. Olson believed the investigation has added a very valuable and definite clinical entity, *i.e.*, "chronic recurring appendicitis." At no time during the clinical development of this syndrome is a definite acute exacerbation seen, but, as the title implies, the disease presents with chronically recurring symptoms and pathological changes as regards the appendix.

Up to date, the diagnosis and classification of chronic appendicitis has not been so uniform and clear-cut in its differentiation in the various medical centers and clinics. It would seem, Dr. Olson went on to say, that a more universal appreciation of the facts that Dr. Peterson has brought out in this excellent paper would clear up many differential diagnoses. Particularly would this be true in the large number of patients with gastrointestinal complaints, often indeterminate and bizarre, where a definite organic basis is difficult to diagnosticate.

Dr. Olson said he would like to ask Dr. Bell and Dr. Peterson under what classification they would put an appendix which is apparently normal in appearance when it is removed between attacks of appendicitis.

Dr. Peterson said he felt that Dr. Bell could answer some of these questions better than he could.

Dr. Bell stated, in reply to Dr. Olson's question, that after an attack of acute appendicitis, whether mild or severe, there is a period of healing which lasts a variable length of time depending upon the severity of the attack. If the appendix is taken out in that interval it shows some lymphocytes in the serous layer. During a second acute attack which may follow there will be be evidence of both the old and the recent attack. The stage of healing is the "interval appendix." In the course of time the healing goes on until there is nothing left. One can't say that the patient never had appendicitis but one can say there is no appendicitis at that particular time. There isn't anything known to the pathologist that is chronic in the sense of a low-grade infection. There are acute exacerbations. Everyone knows that appendices heal. The appendix which has an obliterated lumen is found in nearly half the adults and in many people who have never had any symptoms. It is found postmortem. And the fact that the patient gets well after the operation does not mean that the operation cured the patient. It might have been some other phase of hospital treatment, diet, etc. And some of the cases which had a normal appendix did not get rid of their trouble. Dr. Bell said that none of the men in their discussions had told him what the pathologists should put on the hospital charts in some of these cases.

Dr. Corbett said he could not help but feel that judgment must come in where arbitrary rule leaves off, and the pathological department should exercise discriminating powers. The unprincipled man should be brought to light but careful conscientious surgeons sometimes remove a normal looking appendix and care should be exercised that such cases were not made to serve the ends of the shyster lawer. The only chronic appendicitis he could recall was one that had a pin sticking through it. In addition an appendix, once the site of rupture and an abscess, proved normal on examination when it was removed six months later.

Dr. J. A. Johnson said he could not see that there is anything to hide in these cases. Why not be perfectly frank in regard to the appendix? Why not call them "inactive appendicitis," for that is what they really are?

Dr. S. R. Maxeiner was of the opinion that Dr. Bell's statement, "No acute inflammation to be found at this time," covers the situation very well. No one could tell definitely what had taken place before that.

After the scientific program, a short business meeting was conducted. The President called upon the Secretary to read the minutes of the October meeting, and these were approved as read. The Secretary reported that the Council had already approved the application of Dr. H. M. Lee and his name should be voted upon at this meeting.

Upon ballot, Dr. Lee was unanimously elected to membership in the Society.

The President reported that the matter of a new lantern had been investigated further, and it was decided to continue using the small lantern for ordinary slides and the one in the auditorium for microscopic slides when necessary.

The meeting adjourned, after the President called upon the members to send in the titles of interesting case reports so that the programs for future meetings might be arranged satisfactorily.

H. O. McPheeters, M.D., *Secretary.*

THE ABSORPTION OF LEVULOSE

Various investigators have asserted that levulose is particularly valuable in the dietary of patients with diabetes. Perhaps the most enthusiastic report, among the conflicting statements, is that of Joslin, who is inclined to believe that levulose can be used with advantage in the diabetic diet in small amounts daily for intermittent periods. Levulose seems to cause a different type of metabolism from dextrose, possibly because of the conversion of levulose in part into fat in diabetes or to a more active stimulation of the production of insulin. A recent investigation has shown that levulose is not changed to dextrose in the intestines. Whatever transformations occur take place beyond the seat of absorption. (Jour. A. M. A., October 24, 1931, p. 1230.)

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

EYE, EAR, NOSE AND THROAT

THE SIGNIFICANCE OF THE SQUAMOUS EPITHELIUM IN THE CAUSE AND REPAIR OF CHRONIC MIDDLE EAR DISEASE: Ralph Almour (Trans. Amer. Acad. of Ophthalm. and Otolaryng., 1930, pages 357-377). According to Wittmaack the normal process of pneumatization consists of three stages: first, the ingrowth of subepithelial connective tissue into the marrow spaces; second, the contraction of the subepithelial tissue; and third, the sinking in of the epithelial covering.

The catarrhal type of infantile otitis results when meconium or any other foreign body finds its way into the middle ear during the early stages of respiration. A foreign body irritation occurs producing localized destruction of areas of the epithelium in the middle ear and later hyperplasia of connective tissue. Thus the process of pneumatization ceases at the end of the first stage. A metaplastic bone formation occurs resulting in what we call a sclerotic mastoid process.

If suppuration occurs, the type of mastoidal structure found will depend upon what stage of pneumatization had developed within the mastoid at the time of the onset of infantile suppuration. If suppuration sets in before the first stage, a mastoid will be developed with its spaces filled with marrow, and it is termed diploetic. If suppuration occurs in the first stage, a partially pneumatized mastoid process results.

The development of chronic suppurative otitis media depends on what degree of pneumatization has occurred in the mastoid. An individual with a normally developed mastoid will develop an acute mastoiditis from a suppurative middle ear condition rather than a chronic aural suppuration. An individual with a faulty pneumatization of the mastoid cannot develop an acute mastoiditis. In this case the aural suppuration will produce an acute otitis media which will heal or produce a chronic suppuration of one form or another.

There are two types of chronic otorrhea—tympanic mucosal suppurations and suppurations kept up by the ingrowth of squamous epithelium. The type of mucous membrane remaining after the catarrhal type of otitis media neonatorum is a hyperplastic mucosa. The tendency for an acute suppurative otitis to develop into a chronic purulent otitis of the catarrhal type depends upon the degree of hyperplastic mucosa present as a result of infantile otitis of the catarrhal variety. This type is always associated with a large persistent central perforation of the drum. The squamous epithelium grows through the perforation from the outer to the inner surface of the drum. The mucosal epithelium, being higher at the periphery, resists the ingrowth of squamous epithelium here. When the ingrowth of squamous epithelium is stopped, the size and shape of the perforation does not develop any further.

The second type of chronic otorrhea is dependent upon the ingrowth of squamous epithelium into the middle ear and its adjoining spaces. This type also depends on the previous occurrence of an infantile catarrhal otitis. For the development of this type adhesive bands must be present. These afford easy access of epithelium into the middle ear. As the epithelium grows into the middle ear it replaces the mucosal epithelium. Where the two kinds of epithelium meet, there appear to be granulations. The squamous epithelium undergoes its normal process of desquamation and these products act as an irritant to the mucosal epithelium. This produces a chronic inflammation of the mucosa which in turn acts on the squamous epithelium, producing a condition similar to eczema. Usually the ingrowth of squamous tissue continues until the entire middle ear is covered with it.

Squamous epithelium also takes part in the production of a cholesteatoma. The middle ear and accessory spaces are completely filled with the products of epithelial desquamation. These are not thrown off but accumulate and cause a definite increase in the size of the spaces.

A cholesteatoma may be primary or secondary. If primary, it is formed without inflammation. It usually occurs from mechanical causes. The adhesive bands which are present in the middle ear may separate the aditus and antrum from the tympanum. The air is absorbed in the walled off aditus and antrum, Shrapnell's area of the drum is subjected to negative pressure, a transudate occurs in the middle ear, Shrapnell's membrane recedes until it reaches the walls of the antral space, it becomes adhered here and finally ruptures from the negative pressure. The squamous epithelium then rapidly proliferates into the aditus and antrum, the products accumulate and a cholesteatoma forms.

Another form of chronic purulent otitis media due to the catarrhal type of otitis media neonatorum is that which occurs in scarlet fever and in connection with debilitating diseases like diabetes or nephritis. It is produced by a widespread thrombosis of the vessels of the submucosa leading to a mass necrosis of the mucous membrane. In severe cases the periosteum becomes involved. If all the mucosa is not destroyed, healing may occur from regeneration of the remaining mucosa. In cases where the mucosa is entirely destroyed, healing occurs through the ingrowth of squamous epithelium. If the antral lumen is retained as such, the epithelium grows into it and forms a secondary cholesteatoma.

James Brusegard, M.D.

GYNECOLOGY AND OBSTETRICS

GUM ACACIA IN THE TREATMENT OF ECLAMPSIA: William J. Dieckmann (Am. Jour. Obst. & Gynec., Vol. XXII, No. 3). The author postulates that in eclampsia there is an absolute or a relative decrease in blood volume with abnormal concentration. This explains many of the chemical changes described by various investigators. The faulty circulation leads to "tissue acidosis" and accumulation of waste products. The concentrated blood has a short coagulation time, predisposing to intravascular thrombosis and to the pathological lesions characteristic of eclampsia.

It is generally accepted that during normal pregnancy there is a true hydremia which may be accentuated in pre-eclamptic conditions. During eclampsia there is a concentration similar to that seen in shock and burns. The condition requires a form of treatment which will replace water in the circulation and retain it there. The use of glucose solution intravenously is usually effective and leads to clinical improvement. In certain cases, however, the dilution could not be maintained. For these, blood transfusion is not advisable because of the already high hemoglobin, cellular content, and viscosity. On theoretical grounds the author believed that gum acacia solution would serve to accomplish this purpose.

His clinical experience with a small number of cases confirms this idea. He advises the use of from 500 to 1,000 c.c. of a 6 per cent solution of acacia prepared by Eli Lilly & Co.

He concludes: The principal change in the blood in eclampsia is a concentration which may be absolute or relative. Relief of this condition is usually accompanied by clinical improvement. Hypertonic glucose has previously given the best results in relieving this condition.

Gum acacia solution has cured patients who did not respond satisfactorily to our usual methods of treatment. The probable explanation is that an injection of the gum acacia solution increases the blood volume, lowers the viscosity and thereby improves the circulation through the tissues.

A. L. McDonald, M.D.

EPINEPHRIN IN THE TREATMENT OF THE DYSTOCIA OF DEMELIN (Spastic contraction of the uterus): Pierce Rucker (Gynecologie et Obstetrique, Vol. XXII, No. 5). The author reviews experiments conducted upon the uterus during labor showing the effects of epinephrin 0.3 c.c. of a 1 to 1,000 solution given hypodermically, resulting in a definite and constant arrest of uterine contraction for a period of from nine to thirty minutes. These findings have been confirmed by other independent investigators.

The action of epinephrin upon the uterus during pregnancy and labor has the following applications.

1. To prevent abortion or premature labor. The use of 0.3 c.c. of a 1 to 1,000 solution of epinephrin has proven more efficacious than morphine or atropine.
2. To overcome the effect of uterine hypertonus or contracture in prolonged labor. The same medication gives satisfactory rest and relaxation, after which labor proceeds normally.
3. In cases of prolonged labor complicated by annular contracture, the so-called "Bandl's Contraction Ring," hypodermic injection of 0.5 c.c. of a 1 to 1,000 solution of epinephrin was followed by a period of relaxation greater than that produced by anesthesia alone, and sufficiently prolonged to permit of surgical delivery by version or forceps.

MEDICINE

A STUDY OF FIVE HUNDRED DIABETICS: Elmer L. Sevringhaus, M.D. (Amer. Jour. of Med. Sci., September, 1931). This article is of considerable interest to the practitioner who is treating diabetics. This is a study of five hundred cases which were admitted to the Wisconsin General Hospital. These cases came from rural districts.

Of these five hundred cases, 60 per cent required insulin on discharge.

Pulmonary tuberculosis, which has been said to occur in about 4 per cent of diabetics, was found in only about 2 per cent of this series. This may be explained in the fact that these patients came from rural districts.

Pain in the extremities, which is a rather frequent complication of diabetes, occurred in 36 per cent of this series. As a therapeutic measure they recommend alternate warm and cold applications, but they recommend highly the use of the Buerger passive exercises for the legs, which has given real symptomatic help in many instances. However, the relief from pain does not become evident until the exercises have been used for three or four weeks. Leg pains in the second and third decades are commonly of the cramp type, and are promptly relieved when diabetic therapy is adequate.

The causes of death include sepsis, cardiovascular-renal disease, and coma, in the order of importance. Pyogenic infection after gangrene, and pneumonia, are the commonest infective processes leading to death. The significance of cardiovascular-renal disease in the diabetic is discussed, and is of such a common occurrence that it should receive more consideration than it usually does.

The occurrence of ketosis at the time of admission, or first examination, is shown to be a good evidence of the need of insulin. This, again, is a practical point worth keeping in mind.

RICHARD BARDON, M.D.

PNEUMOPERITONEUM IN THE TREATMENT OF TUBERCULOSIS: Andrew L. Banyai, M.D., Muirdale Sanatorium, Wauwatosa, Wis. (Amer. Jour. Med. Sci., Sept., 1931). The author in a résumé of tuberculous enterocolitis emphasizes the frequency of tuberculous ulceration (60 to 90 per cent) in autopsies. Steinbach noted 61.5 per cent of 127 positive autopsy findings in which the condition had not been recognized during life from absence of physical signs. Attention should be paid to all forms of gastro-intestinal distress and of *nervous irritability* and the fact the patient is not doing well. Diarrhea is not characteristic of ulceration of the large intestine. Rigidity of the abdominal wall is indicative of disease of the serosa.

While it is possible to establish a diagnosis upon these symptoms and physical findings, alone, the X-ray should corroborate all cases. The Stierlin sign—a filled terminal ileum and filling-defect in cecum and ascending colon—receives due emphasis. Diagnosis may still fail in some cases because of the absence of subjective signs, and of the unreliability of roentgenologic findings. Therapeutic pessimism is not justifiable because healed ulcerations are noted clinically and by postmortem examination.

The cure is dependent partly upon early diagnosis. "The only proper method is to anticipate symptoms" (Stewart). The treatment should be (1) prophylactic, (2) dietetic, (3) medicinal, (4) radiational, (5) surgical, (6) pneumoperitoneal. The prophylactic treatment includes HCl to prevent anacidity. The diet should be small in bulk, cellulose-free, of easily-assimilable foods, of smooth consistency. Liquid foods are required when there is much diarrhea. Entirely salt-free diet is badly borne.

The medical treatment includes calcium intravenously, and bismuth, astringents, atropine and opium. Radiation by natural and artificial sunlight yielded 85 per cent symptom-free after six months' treatment.

Early exploratory laparotomy is used only in mildly active or quiescent pulmonary disease without marked gross anomalies, on constitutional symptoms, also in cases in which the roentgen findings and physical signs indicate a well localized lesion of cecum or ileum occurring late in chronic or intermittent types of pulmonary diseases.

Pneumoperitoneum with oxygen was used by Banyai in 44 per cent of his cases. Time: between breakfast and lunch. The bladder was emptied before operation. Enemas and cathartics avoided. Codein was given for cough. Site of entry—three fingerbreadths below and left of umbilicus. Anesthetic 1 per cent novocain. A small skin-incision admitted the Floyd-Robinson needle, which was slanted upwards towards the mid-line. Manometer readings are made as in pneumothorax, but are not of as great value as in the thorax. The intra-abdominal pressure is neutral in untreated cases. The operator judges chiefly by the lack of resistance when the needle enters the peritoneal cavity. Positive pressure occurs usually after 300 to 500 c.c. of oxygen. The disappearance of dullness and the subjective impressions of the patient are useful guides. Absence of liver dullness follows full doses. From 300 to 1,200 c.c. are used. The largest amount injected was 1,500 c.c. The smallest 150 c.c. There may be discomfort due to tension. The patient is usually allowed to walk back to his room and the daily routine is not changed except when there is discomfort from over-tension. Under-inflation rather than over-inflation is desirable. The mechanical effect of oxygen upon the lesions is not exactly known. Oxygen increases all cell-activity. It is known to cause irritation of the peritoneum and serous larger of the intestinal wall. A decrease in peristalsis was noted. The ideal includes maximum immobilization, improved nutrition, immune-body supply, stimulation of phagocytosis and the neutralization of toxic products. The essayist used the procedure only in those cases which did not show a satisfactory response to dietetic and medicinal treatment. Symptomatic relief was shown in 70.4 per cent. Complete relief was seen in 31.8 per cent. No relief in 29.6 per cent. The results were considered sufficiently encouraging to warrant a more frequent use of the method.

J. G. LAMONT, M.D.

PEDIATRICS

TREATMENT OF WHOOPING-COUGH WITH CONVALESCENT SERUM: J. C. S. Battley, M.B. (Tor.), Port Huron, Mich. (Arch. Ped., Vol. XLVIII, No. 10, October, 1931). Forty infants, who undoubtedly had been exposed to others suffering from whooping-cough, were given two to three c.c. of pooled serum taken during the fourth week of illness, at which time it had been found that the antibody content of the serum was highest, as shown by complement fixation tests. Of these patients, thirty-one were entirely protected, six had a mild illness, and three had the usual attack. Debre concluded that if the serum is injected before the end of the incubation period the onset of illness is prevented, if at the end of the incubation period the disease appears in mild form, if during the invasion period it is not affected. Gillot gave whole blood subcutaneously, taken from persons who had had whooping-cough a long time before, in a series of children from one month to six years of age. He found that four children injected before the catarrhal stage began were completely protected and two injected during the catarrhal stage suffered from a mild attack. In another series, blood of fathers and mothers without a history of whooping-cough was used. Six children injected before the catarrhal stage escaped the disease and five injected during the catarrhal stage had a mild attack. Doses of two to four c.c. of blood were used, the larger for the older children.

Convincing evidence of the value of convalescent serum must await extensive observation. Meanwhile, convalescent serum or convalescent whole blood, or even the blood of persons who have had whooping-cough in childhood, should be worthy of trial for prevention and treatment.

R. N. Andrews, M.D.

ROENTGENOLOGY

THEODOR BARSONY AND ERNST KOPPENSTEIN: CONCERNING THE SHADOWS IN THE UPPER LUNG-FIELD (Fort. a. d. Geb. der Roentgenstrahlen, September, 1931, 44:320). The authors discuss the appearance and significance of certain little known or confusing shadows in the upper lung fields. The "companion-shadow of the second rib" (of Albers-Schönberg), the "lateral companion-shadow," and the "medial curved shadow" (now described for the first time) are all normal manifestations but are of importance as they occur in regions susceptible to pathological changes. Each is illustrated and discussed in detail. Figures are given for the frequency of the occurrence of each in roentgenograms of 200 lung apices.

A triangular shadow with its broad base lying against the chest wall may occasionally represent the upper end of an atypically placed main interlobar fissure.

At the medial angle of the scapula is a round soft tissue shadow which represents the attachment of the upper portion of the serratus anterior muscle.

The shadow of a deep-seated groove for the clavicle may be mistaken for a cavity, while the summation shadow of the sterno-cleido-mastoid and the first rib may simulate an adhesion.

Frederick B. Exner, M.D.

MEDIASTINAL TUMORS AND THEIR COMPARATIVE SENSITIVITY TO IRRADIATION: S. Lamarque and J. M. Bert (Jour. de Radiology et Electrology, August, 1931, XV, No. 8, pp. 416-26). The authors have seen two cases of mediastinal tumor recede under X-ray therapy and compare the response to treatment in the two cases according to sensitivity. The first case was a girl of fourteen years who had a mediastinal lymphocytoma that completely disappeared in eight months under X-ray therapy and had not recurred after two and one-half years. The second case is a man of twenty-seven years who had a lymphogranulomatosis (Hodgkin's disease) that disappeared after one year of X-ray therapy and had not recurred after nineteen months.

Mediastinal tumors may be divided into lymphoid and non-lymphoid types. The lymphoid tumors may occur with or without blood changes, and the response to X-ray therapy is good although the ultimate prognosis is bad because of recurrences. The response to therapy is not as good in Hodgkin's disease and the prognosis is poor because of local and general recurrences. Treatment is most effective in the early stages of the disease.

They conclude that histology is the most important factor in treatment. Mediastinal tumors can be classified according to their response to therapy as well as their histologic structure. This constitutes a therapeutic test and the response varies with the type of tumor. Clinical and experimental work has shown good response in lymphoid and hematopoietic organs. X-ray today is the most powerful, curative or palliative treatment of mediastinal tumors although its results are usually temporary.

Jacob Sagel, M.D.

SURGERY

SPLENECTOMY—ITS INDICATIONS AND TECHNIC: David P. D. Wilkie, F.R.C.S., Edinburgh (Amer. Jour. Surg., Vol. XIV, No. 1, October, 1931). This article, which reviews briefly the indications for splenectomy in cases of splenomegaly associated with definite blood changes, is especially interesting for the definite and detailed description of the operative technic, with illustrations. The three blood dyscrasias in which splenectomy is done are briefly described, including splenic anemia, hemolytic jaundice, and chronic purpura. Cases exemplifying each type are reported.

The description of the operation itself is unusually clear, so that it is herewith abstracted verbatim:

"In textbooks of operative surgery no operation is described so inadequately as splenectomy. Whether the spleen be normal in size or grossly enlarged there are certain points in anatomy which must be appreciated if its surgical removal is to be rendered easy and safe. The organ lies very deeply in the left hypochondrium and is maintained in position by the lienorenal ligament up the medial border of which run the splenic vessels. The outer leaf of this ligament is short and in splenomegaly is often thickened. It forms an effective barrier to delivery of the spleen into the wound and it must be divided as a definite step in the operation before any attempt is made to deal with the splenic pedicle. In order to expose the front of this pedicle the gastrosplenic omentum must be divided, the vasa brevia being ligated, and, that ready access to the pedicle in case of mishap may be insured, this should be the first step of the operation. The gastrosplenic omentum is very short at the upper pole of the spleen and care must here be exercised in ligating. It is of advantage to leave this short uppermost portion till a later stage in the operation when complete mobility of the spleen has been secured. That the stomach may not impede the view of the splenic pedicle it is a good practice to pass a stomach tube and leave it *in situ* during the early stages of the operation.

"Now comes the most important step in the operation. A hand is placed over the phrenic surface of the spleen and the organ is gently pulled over to the right. At the same time, the left costal margin is retracted and the outer leaf of the lienorenal ligament, which has been rendered tense, is exposed. With a long-handled knife the peritoneum of the ligament is divided and the spleen comes forward. With a second touch of the knife the thickened subperitoneal areolar tissue or fascia propria is divided and the spleen completely mobilized. No difficulty is now encountered in delivering the spleen in the abdominal wound. The upper end of the gastrosplenic omentum is now readily accessible and the very short vessels running from the stomach to the upper part of the splenic hilum are ligated and divided.

"The main splenic pedicle is now raised on two fingers of the left hand. The splenic artery which lies uppermost is freed, doubly ligated and divided. After a pause to allow of venous drainage and thus minimize loss of blood, the splenic vein is similarly dealt with. The tail of the pancreas can now be dissected off and the spleen removed. There should be no hemorrhage.

"Summarized the steps of the operation are as follows:

1. Anesthesia.
2. Passage of stomach tube.
3. Left paramedian incision.
4. Ligation and division of the gastrosplenic omentum.
5. Spleen gently pulled to right and with a long knife the peritoneum forming the outer leaf of the lienorenal ligament divided. The underlying fascia propria is also divided.
6. Spleen delivered in wound and extreme upper end of gastrosplenic omentum divided between ligatures.
7. Pedicle raised on fingers.
8. Splenic artery doubly ligated and divided.
9. Splenic vein doubly ligated and divided.
10. Tail of pancreas dissected off.

"There is no abdonimal operation in which a deliberate plan, based on antomical knowledge, is more essential than in splenectomy. In dealing even with the largest spleen, hemorrhage need not occur if such a plan be followed, and what some have called adhesions are, I believe, merely anatomical attachments thickened to support the weight of the enlarged organ. Speed is of no importance in the bad risk splenectomy; infinite care to preclude the possibility of hemorrhage is all-important."

A. E. SOHMER, M.D.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

CERTIFIED MILK. Conference held in 1931. 334 pages. Brooklyn, N. Y.: American Association of Medical Milk Commissions, Inc., 1931.

THE HUMAN VOICE. Its Care and Development. Dr. Leon Felderman. 301 pages. Illus. Price, $2.50. New York: Henry Holt & Co., 1931.

HEALTH PROTECTION FOR THE PRESCHOOL CHILD. (The White House Conference.) 275 pages. Price, $2.50. New York City: The Century Company, 1931.

CONQUERING ARTHRITIS. H. M. Margolis, M.D. 192 pages. Illus. New York: The MacMilan Company, 1931.

VERTEBRATE ZOOLOGY. Casey A. Wood, M.D., LL.D., Collaborator, Division of Birds, Smithsonian Institution. 643 pages. Illus. Price, $15.00. London: Oxford University Press, 1931.

A DOCTOR OF THE 1870's AND 80's. William Allen Pusey, A.M., M.D., LL.D. Sometime President of the American Medical Association and the American Dermatological Association. 153 pages. Illus. Price, $3.00. Springfield, Ill.: Charles C. Thomas, 1932.

A NON-SURGICAL CONSIDERATION OF PROSTATIC ENLARGEMENT. Edwin W. Hirsch, M.D. Associate in Urology, College of Medicine, University of Illinois, Urologist, Englewood Hospital, Chicago. 79 pages. Illus. Price, $2.00. Saint Paul, Minnesota: Bruce Publishing Company, 1931.

AN INTRODUCTION TO THE LITERATURE OF VERTEBRATE ZOOLOGY. Based chiefly on the titles in the Blacker Library of Zoology, the Emma Shearer Wood Library of Ornithology, the Bibliotheca Osleriana (the Gest Library of Chinese Literature), and other Libraries of McGill University, Montreal, Canada. Compiled and edited by Casey A. Wood, M.D., LL.D., Collaborator, Division of Birds, Smithsonian Institution. 4to, pp. xix and 643. Col. frontispiece, $15.00 (3 guineas). London: Oxford University Press, 1931.

In an Introduction to the Literature of Vertebrate Zoology, Dr. Wood has written nineteen chapters or about 149 quarto pages in his characteristic and entertaining way from the beginnings of zoological records from early Greek and Oriental zoologists down to the present day. For those who read these chapters, will be found an enormous amount of painstakingly acquired information on all phases of Vertebrate Zoology, and written in a pleasing style which takes on a personal interest for those who know Dr. Wood.

This introduction gives a review and comments on the books, periodicals, and manuscripts contained in the Libraries of McGill University. Their files are replete with rare and important writings in vertebrate zoology and especially in ornithological literature.

This catalogue is indexed under general treatises on vertebrate zoology of the world, subdivided under birds, mammals, fishes, and reptiles and batrachians. This is followed by an index, a geographical catalog under continents, countries, and island groups. The main part of the work follows in 469 quarto pages of alphabetically arranged authors' and periodical titles in the McGill University Libraries. There are throughout the catalog under-titles, comments and résumés by the author which make this work a most valuable catalog for anyone interested in the literature of vertebrate zoology.

John C. Brown.

CONQUERING ARTHRITIS. H. M. Margolis, M.D. 192 pages. Illus. New York: The Macmillan Company, 1931.

On the whole the field for books on disease written for the patient is limited. One is inclined to be rather antagonistic at first to the idea of a book written by a doctor for the arthritic patient. This volume, however, gives the essentials of the present status of medical knowledge about the cause, classification and treatment of arthritis, as well, at least, as can be given on a subject about which medical knowledge is so woefully incomplete. A chronic arthritic patient is so likely to become discouraged and resort to perfectly useless and costly methods, grasping at a straw for some cure, that it seem very probable that this volume will meet a real need.

C. B. Drake, M.D.

THE INTERNATIONAL MEDICAL ANNUAL. Wm. Wood & Co., New York. Price, $6.00.

The 1931 volume of this annual is the forty-ninth of the series. The British editors and contributors have again succeeded in including in this fair sized volume a summary of the progress made in the entire field of medicine and surgery with the exception of pathology. The sources have been international.

Recent work or undulant fever, iodine compounds for intravenous urography, hyperinsulinism, sympathectomy are typical inclusions.

The book is not too large for a complete reading, and solves in part the impracticability of keeping up with the mass of modern medical literature. It should be of particular value to the general practitioner.

C. B. Drake, M.D.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

FOR SALE—Hanovia alpine lamp, large size, alternating current. In excellent condition. Used only short time. Address H. Rushton, 4932 36th Avenue South, Minneapolis. Telephone Dupont 6013.

EXCELLENT LOCATION with internist in outlying district of Minneapolis available for capable Rhinologist and Otolaryngologist. Write details of education, training, experience, reference. Splendid opportunity. Thorough consideration and investigation invited. Address D-156, care Minnesota Medicine.

FOR SALE—Luxor Lamp, Hanovia Quartz. Same as new. Also Mayer & Ellis & Wells works. Will sell cheap. Apply Berkhall Products Co., 12 East 25th Street, Minneapolis.

FOR SALE—Small rural hospital. All modern. Worth $25,000. Will sacrifice for $16,000. Instruments and equipment included. $5,000 cash, balance terms. Address D-157, care Minnesota Medicine.

AN EXCEPTIONALLY GOOD LOCATION for a physician. Call or write C. A. Cavanaugh, druggist, 2901 Washington Ave. North, Minneapolis.

WANTED—Location in Minnesota by Northwestern graduate—age 29. Interned at Ancker Hospital, St. Paul. Desires general practice in town of 1,500 or more, convenient to hospital facilities. Address D-155, care Minnesota Medicine.

OFFICE SPACE for physician and dentist, corner location, Hennepin Avenue and 28th Street, Minneapolis. Address J. R. Hunsaker, West High Pharmacy, Hennepin at 28th, Minneapolis, Minn.

FOR RENT—Doctor's office in conjunction with dentist. Heated, modern, over drug store. Reasonable. Equipment optional. Telephone Dinsmore 0522 (Minneapolis) or address D-158, care Minnesota Medicine.

FOR SALE—Office equipment including X-ray. Location in Minnesota town of 1,400 people. Average income of over $5,000 yearly for the past eight years. Unopposed. Specializing. Address D-150, care Minnesota Medicine.

EYE, EAR, NOSE, THROAT specialist, willing to assist in general practice and surgery, wants association with busy physician or surgeon. Address D-159, care Minnesota Medicine.

THREE GENERATIONS of experience in grinding, specializing in fine surgical instruments. Prices, reasonable. Schwarz Grinding Service, Foot-Schulze Bldg., 128 10th St. E., St. Paul. Telephone, Midway 9939.

LUMBAR ANESTHESIA—RÉSUMÉ OF 751 CASES*

W. C. STILLWELL, M.D., F.A.C.S.
Mankato, Minnesota

WE find that our patients are much less apprehensive when we refer to "lumbar" instead of "spinal" anesthesia. A more correct term would be spinal subarachnoid block instead of subdural or intradural anesthesia as it is so often wrongly termed in our literature. Placing the anesthetizing drug under the dura instead of under the arachnoid membrane is a frequent cause of failure in obtaining a good anesthesia.

Lumbar anesthesia was first discovered by J. P. Corning in 1885, when he accidentally punctured the spinal membranes while injecting cocaine into the spinal region to control pain. Bier and Hildebrand in 1898 had the courage to demonstrate upon themselves. They injected .5 c.c. of 1 per cent cocaine solution into the spinal canal of each other. The anesthesia was apparent only in Hildebrand. Failure to obtain anesthesia in Bier was due to a leaky syringe and most of the cocaine solution was lost. Hildebrand described thoroughly the effects of the anesthesia as they developed and then later disappeared. He was quite sick for several days following the injection. Only during the past few years has lumbar anesthesia emerged from its slumbers to take its rightful place among the various methods of anesthesia. The work of Babcock, Labat, Jonnesco, Koster, Evans, Pitkin and others has done much to eradicate our doubts and misgivings and to place lumbar anesthesia on a definite comprehensible basis.

In our series, lumbar anesthesia was induced in the great majority of cases by the so-called "volume speed control method." This method was adopted after trying various other methods, which had given equally good results in other hands. The novocain or neocain crystals are dissolved in the spinal fluid and this solution is re-injected into the subarachnoid space without barbotage, thus obviating the chance of misplacing the needle during such maneuvers. It is probably the most simple and least technical of all methods.

Kirschner has recently devised a method by which he induces a belt anesthesia which is limited to the field of operation. He places the patient in the lateral position with the head down, and after inserting the needle (which has special features) into the spinal canal, he replaces the spinal fluid in the lower part of the canal with air. He then introduces his anesthetizing solution of lesser specific gravity than the spinal fluid and this floats on top of the spinal fluid, causing a localized anesthesia. He has devised a spinal double syringe to facilitate the injection of both air and the anesthetizing solution in varying amounts.

Preoperative medication has varied but usually consists of a sedative the evening before operation, and morphine sulphate, gr. 1/6 by hypodermic with nembutal, grains 3, per os, one hour before operation. This usually allays all nervousness and eradicates any psychic trauma. It is often noticed that a restless patient will become very quiet and go to sleep during a high abdominal anesthesia. Such an effect cannot be attributed to vascular depression as it occurs when the blood pressure has remained normal. This phenomenon may be due to the blocking of adrenal glands through the sympathetic system, or to a high diffusion of the drug to the cerebral cortex.

The dosage of novocain used has varied from

---

*Read before the Southern Minnesota Medical Association, Faribault Minnesota, August 24, 1931. Since this paper was written the series of lumbar anesthesia cases has been increased to over 1,000 cases.

50 to 350 mg., and is gauged according to age, weight, general condition of patient, level and duration of anesthesia desired. Ephedrine sulphate is given subcutaneously in doses of 30 to 120 mg., at the puncture site. Although Labat emphatically states that ephedrine should not be used and apparently proves his statement from a theoretical standpoint, practical experience has proven that ephedrine has the desired effects and that it has a definite place in lumbar anesthesia. Ephedrine has a peripheral vasomotor action, especially upon the splanchnic vessels. We have omitted the ephedrine several times and have noticed a greater drop in blood pressure.

Our patients are not immediately placed in the Trendelenburg position, but are kept horizontal for 10 to 12 minutes until the drug becomes fixed. Later they may be placed in the Trendelenburg position if desired for better exposure of the operative field. However, in doing a cholecystectomy it is advantageous to keep the patient in the horizontal position so that the liver can be readily turned down and outward. In case of a sharp drop in blood pressure or evidence of shock, the table is at once tilted into the Trendelenberg position, but the necessity for this maneuver has been uncommon in our series. Following the operation the foot of the bed is elevated for several hours.

We can usually start the operation five to seven minutes following the injection, but occasionally it is necessary to wait longer. If the anesthesia is not satisfactory or high enough after five minutes we usually lower the head of the table to allow the drug to diffuse higher. This maneuver will be of little value if done after 10 minutes or more.

Table I shows the type of cases and is self-explanatory. It might be said here that most of the poor results were encountered during the early part of the series, and were probably due to faulty technic. At times when the operation has been prolonged over 60 or 70 minutes, it has been necessary to supplement with nitrous oxide-oxygen anesthesia. However, this can be avoided if larger doses of novocain are used.

Table II is a classification of the complications and sequelæ which may follow lumbar anesthesia.

Low blood pressure or vascular depression is due to paralysis of the vasomotor center, especially affecting the great splanchnic pool, which is controlled by nerves from the region of the

TABLE I

TYPE OF OPERATION	LUMBAR ANESTHESIA

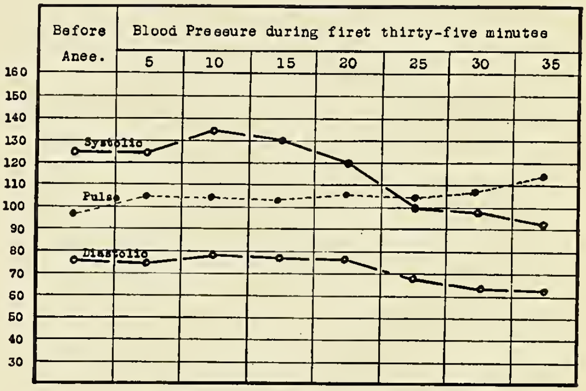
2. Nerve Injuries
3. Psychic Disturbances

Chart II shows the average blood pressure during the first 35 minutes in eight radical breast operations. Here the blood pressure showed a greater drop and the pulse quickened. Large doses of novocain were used in these cases because of the height of anesthesia desired and the length of time which might be required for completion of the operation. This type of case is greatly benefited by the intravenous injection of normal saline during or immediately after the operation. Larger initial doses of ephedrine may be given, the small initial dose may be supplemented later, or one of adrenalin may be given.



Average Blood Pressure and Pulse - Eight Cases
Radical Breast Operation - Lumbar Anesthesia

Chart II

Hypertension cases show a greater drop in blood pressure, which may be due to the fact that ephedrine acting as a peripheral vasoconstrictor has less effect upon sclerotic arteries. Hypotension cases respond very nicely to ephedrine and, at the end of the operation, their blood pressure is often higher than before. We do not hesitate to use lumbar anesthesia because of hypotension unless this is due to a moribund condition or to great general debility.

In observing blood pressure readings it is a common mistake to consider only the systolic or driving force of the heart, and to disregard the diastolic pressure, which represents the tone of the peripheral vasomotor capillary bed. Life is dependent upon the diastolic pressure and when it falls below 40 mm. Hg. the oxygen dissociation curve reaches a point where oxygen is no longer available when the blood reaches the capillaries. At 60 mm. Hg. (MacLeod), the blood may be nearly saturated with oxygen, whereas at pressures below 50 it readily loses oxygen, and at 10 there is a complete loss of oxygen. It is therefore imperative that we keep up the diastolic pressure.

Nausea in this series has been present but not annoyingly so, and it has been less noticeable during the past few months. At times it seems that overaction of the ephedrine might be the etiologic factor in some cases. We recognize three types of nausea:

1. That due to psychic causes, evident when the patient is allowed to over-indulge in conversation. A few deep breaths usually suffices to stop this type.

2. Nausea due to lowered vascular tension. Treatment of this type is that of the low vascular tension.

3. Reflex nausea due to pulling or tugging of intra-abdominal viscera. This type usually stops as soon as the tugging ceases. Inhalation of oxygen with or without CO_2 is often of value in all three types of nausea.

Pallor or cold sweats are usually the result of mild shock which follows a marked drop in blood pressure. This has been quite infrequent but is a danger signal and calls for immediate action. Placing the patient in the Trendelenburg position usually suffices. It is advisable to have intravenous normal saline available for prompt use, if needed.

Respiratory failure is a greatly feared complication, which has done much to keep lumbar anesthesia from gaining widespread popularity. This much talked of complication has been attributed to the high diffusion of the drug in the spinal canal with its paralyzing action upon the respiratory center. However, it is the consensus of opinion that the dilution of the drug, by the time it reaches the bulbar region, is so great that it is almost impossible to paralyze the respiratory center by injecting the drug in the lower spinal region.

Koster has shown by animal experiments that the medulla is not affected by direct application of a 4 per cent novocain solution. Therefore it seems probable that respiratory failure is a result of bulbar anemia and should be treated as such. In lumbar anesthesia to the nipple line one often notes a slight degree of respiratory depression, such as shallow breathing or the patient may complain of a sense of constriction across the chest. Careful observation of the patient during the anesthesia is quite essential. We take blood pressure and pulse readings every five minutes and carefully note the patient's color. In fact, by watching the patient's face one can tell almost as much concerning his condition as by taking the blood pressure.

It is difficult to estimate the amount of vascular depression before an anesthetic is given. Often we have encountered a marked drop in blood pressure following a very low spinal tap, and when only 50 mgm. of novocain was injected. This is probably explained as a vasomotor reflex, due to the spinal tap itself. A marked drop of blood pressure is often encountered following a diagnostic spinal puncture.

Shock and syncope may immediately follow a lumbar puncture regardless of whether any drug is injected into the spinal canal. We have never seen such a reaction. Convulsions are possible when the drug is injected directly into one of the venous sinuses, which are plentiful surrounding the vertebræ.

Among the intermediate sequelæ we find that headache is the most frequent. It may vary from a mild type which clears up readily, to a more severe persistent type which requires careful treatment. In this series, headaches have been conspicuous by their infrequency and have usually occurred in patients who were allowed to be up within forty-eight hours following the operation. We recognize two definite types of headache: The mild type caused by reduced intraspinal pressure following leakage of fluid from the site of puncture, and the severe type due to increased intracranial pressure, probably due to irritation of the spinal membranes by the novocain, red blood cells in the spinal fluid caused by trauma, or foreign material entering at the time of injection. The mild type has always responded when the patient was placed in a recumbent position and on three occasions the headache disappeared after giving 0.5 c.c. of surgical pituitrin subcutaneously. Hypotonic solutions intravenously are also indicated in this type of headache. The severe type of headache has been encountered only a few times and has always responded to a hypertonic solution of glucose given intravenously. Spinal drainage may be used if the hypertonic solution does not relieve. Caffein sodium benzoate in 5 grain doses given intravenously will also markedly reduce the intracranial pressure.

Backache is a common complaint often made by the patient, who naturally believes that the needle inserted into the back is the cause of his pain. As a matter of fact, the majority of patients develop some backache post-operatively regardless of the type of anesthesia. Only a localized aching or pain can be directly attributed to the lumbar puncture. We have had patients complain that their backache is at the point of insertion of the needle, but upon asking them to locate the exact spot, we find it several inches away from the site of puncture. Lumbar anesthesia causes such a complete relaxation of the muscles that it is advisable to place a small hard pillow in the hollow of the back during the operation.

Bladder disturbances have not occurred more often in this series than have been encountered in cases where general inhalation anesthesia has been used.

Meningismus, ocular manifestations, and meningitis have not been encountered.

Late Sequelæ.—Persistent headache is probably due to meningeal irritation with increased intracranial pressure and an increased spinal fluid cell count. Iason, Lederer and Steiner have made studies of the spinal fluid following lumbar anesthesia and have found an increased cell count, and increased sugar reaction, in about 50 per cent of the cases. The headache is usually accompanied by some vertigo, stiffness of the neck muscles and other signs of meningismus. There have been no persistent headaches in this series.

Nerve injuries may be caused by careless lumbar puncture, and may manifest themselves in the form of paresthesia, anesthesia, paresis, sharp shooting pains into the lower extremities, and neurotrophic disturbances. They are, however, infrequent and have caused us very little concern. During lumbar puncture, on several occasions, the patient has complained of a sudden sharp pain shooting into the leg. This evidently was caused by the needle striking a fibre of the cauda equina, but has been of a transient nature.

Psychic disturbances, of which much has been written, have caused us no trouble and probably will not occur if proper pre-operative medication is prescribed.

Morbidity and Mortality.—Morbidity in lumbar anesthesia is certainly minimal. The small amount of novocain used has very little, if any, effect upon the tissue cells, and the kidneys, liver, brain and lungs show practically no toxic effect from the drug. Pulmonary complications are rare compared to those following inhalation anesthesia. In this series there have been several minor pulmonary infections but no post-operative pneumonias. We have encountered one case of massive pulmonary collapse.

Tendler reviewed 326,910 cases in which lumbar anesthesia was used with eighty deaths. His tabulation includes many different technics and drugs used. There are seven series of cases, totaling 22,365, in which there were no deaths. Tendler remarks that including all cases the mortality is one in 4,086 cases. However, in carefully reviewing these deaths, he finds that the greater number were in cases where approaching death was plainly evident, and death would probably have resulted regardless of the kind of anesthesia induced. In only nine or ten cases of the entire series was it evident that death was caused by the intraspinal injection. There have been no deaths directly resultant from the anesthesia in this series, but I wish to report one case in which the patient died about ten days after operation, of what appeared to be a clinical tetanus.

The patient was thirty-four years old, and was considered a good surgical risk. She was given lumbar anesthesia and reacted normally throughout the operation, which consisted of a colpoperineorraphy and a laparotomy for cystic ovaries and retroverted uterus. She convalesced nicely until the evening of the eighth day, when she complained of a headache and some stiffness of the muscles of the neck and jaws. During the night she developed a spasm of the jaws and bit her tongue several times. The next morning there was some stiffness of the masseters, and a slight rigidity of the neck. No Kernig or other abnormal reflex was demonstrated. She complained of some difficulty in swallowing and was quite irritable. Lumbar puncture revealed a clear fluid under slightly increased pressure. Examination of the fluid revealed a low normal cell count and no other abnormalities. That night she developed more stiffness of the jaws and dysphagia was more evident, simulating a hydrophobia. Reflexes at this time were equal but hyperactive. Another lumbar puncture revealed a clear fluid under slightly increased pressure and a normal cell count. Antitetanic treatment was instituted, and she appeared somewhat improved until the next morning. At this time the typical "risus sardonicus" was present. She developed tonic spasms of the diaphragm and died during the third spasm. Complete autopsy was refused but we were allowed to cut out the abdominal wound for examination. A cisterna puncture done at this time revealed another normal spinal fluid cell count. Thinking of a possible tetanus infection from catgut, we excised the abdominal wound and sent it to the laboratory for examination. The report later returned negative for tetanus. Later it occurred to us that we should have taken the perineal wound as well because of the possibility of tetanus infection following perineal and rectal surgery. Tetanus following surgery of this type is mentioned quite frequently in the foreign literature. There was no history of previous injury where the infection might have gained entrance. We do not believe this death can be attributed to the lumbar anesthesia.

Contra-indications for lumbar anesthesia may be grouped as follows:

1. It should not, under any circumstances, be employed in cases presenting involvement of the nervous system, such as brain tumors, meningitis, or intracranial hemorrhage.
2. It should not be used where local infection is present at the site of puncture.
3. Sub-standard risks should not be subjected to this type of anesthesia, except by those who are well trained in its use and who are able to combat any complication which may arise.
4. Grave icteric patients and those with marked cachexia do not stand any sudden change in the vasomotor system, and therefore should not be given lumbar anesthesia. Local infiltration is the method of choice in these cases. We have refused lumbar anesthesia on two occasions and have later seen the patient succumb on the operating table under infiltration anesthesia.
5. Patients in severe shock should not be subjected to lumbar anesthesia until measures have been introduced to raise the vasomotor tone. Patients in shock due to marked hemorrhage react poorly under this type of anesthesia, and are bad risks unless the bleeding is under control and blood transfusion is available. Shock not due to hemorrhage is not to be considered a contra-indication as favorable reactions occur with this method when properly used.

Conclusions.—We believe that lumbar anesthesia in competent hands is the safest and most satisfactory of all forms of anesthesia. Any surgeon who once becomes familiar with its ease of administration and its advantages both to the patient and himself, will never want to go back to other methods. The complete relaxation of the muscles (which is found only in the deep stages of ether anesthesia) and the quiet abdomen facilitate rapid and thorough surgery. During the anesthesia it is found that active intestinal peristalsis is present and that the kidneys show an increased urinary secretion. Post-operative complications are fewer, and much less severe than with inhalation anesthesia. Nursing care has been reduced to a minimum due to the lack of post-operative vomiting and abdominal distention. With the advent of newer and better drugs along with new technics, it is possible that a more localized and longer anesthesia may be available in the near future.

In summing up, I might quote Babcock, who says, "When properly employed, no other anesthesia of equal range leaves so few sequelæ."

ACHLORHYDRIA AND HYPOCHLORHYDRIA IN PEPTIC ULCER*

J. Allen Wilson, Ph.D., M.D., and George Earl, M.D., F.A.C.S.
Saint Paul

THE relationship between peptic ulcer and the acid content of the stomach is complex and has been the basis for many heated arguments between groups of internists and between internists and surgeons. Practically no one believes that hyperacidity *per se* can cause the formation of a peptic ulcer but it is very generally believed that hyperacidity prevents the healing of an ulcer.

Just what are the normal acid values determined with the Ewald test meal? Dr. B. W. Sippy and his successors have made a rough clinical grouping as follows: normal adult free hydrochloric acid ranges from 20 to 40 points; normal total acid values range from 40 to 60 points. Peptic ulcer typically causes higher acid values. This has been a fairly satisfactory standard for duodenal ulcers, though not so well adapted for gastric ulcers, since many gastric ulcers have acidities well within these so-called normal limits. Recently, Vanzant[1] has attempted to establish the normal range of gastric acidity from youth to old age by studying 16,000 records of patients having had gastric analyses. Of these, 3,381 were selected as having no evidence of disease of the gastro-intestinal tract, nor other serious conditions. To these he added data from 365 cases from the literature, in the younger age groups. The test meal used consisted of 8 arrowroot cookies and 400 c.c. of water. If no free HCl was found at the end of an hour, further tests were made each 15 minutes for 45 minutes longer. True achlorhydria was diagnosed only when the fractional test showed no free acid and this was confirmed by histamine injection. The incidence of achlorhydria was found to increase from 4 per cent at 20 years to 26 per cent at 60 years. The one-hour test showed considerably more apparent achlorhydria than was determined with the 1 and three-fourths hour fractional test or histamine injection. He found the typical free acidity in adults to be 35 units in females and 50 units in males. After the age of 50 this sex difference is reduced till at 65 years the males' free acid dropped to that of the females. He suggests that the three-times greater incidence of ulcer in men than in women may be associated with this decided sex difference in acidity. The total acid for adult females remained at about 51, whereas for males it ranged from 66 at 20 years to 56 after 65 years.

The incidence of hyperacidity and achlorhydria in cases of peptic ulcer has been variously reported. A complete review of the literature will not be attempted here, but reference will be made only to a few of the more complete and more recent studies. Rehfuss[2] in his book quotes Bell and Hunter as finding 70 per cent hyperacidity and no achlorhydria in duodenal ulcers. He himself found 78 per cent hyperacidity in duodenal ulcer. Moynihan is quoted as reporting 72.7 per cent hyperacidity for duodenal ulcers but only 20.9 per cent for gastric ulcers. The same author reported 13 per cent achlorhydria in gastric ulcers and 5.5 per cent achlorhydria in duodenal ulcers. The fractional method was used in these cases and the lesions were demonstrated at operation. Histamine was not used. Rehfuss states that the incidence of hyperacidity in gastric ulcer is no greater than the high acid values found in an equal number of normals, but the quantity of total acid by volume may be greater, due to a greater rate of secretion. He emphasizes the fact that gastric secretion *per se* does not produce ulcer, but in the presence of focal infection and other factors, it causes an extension and persistence of the lesion.

Brown[3] in a review of 1,224 cases of peptic ulcer gives figures showing hyperacidity in 75 per cent, normal values of free acid (20-40) in 22 per cent and below 20 points in only 3 per cent. From personal contact with the figures contained in this review, one of the present writers (J. A. W.) does not know of any case of true achlorhydria in this series. Several cases showed no free acid with an Ewald meal, but a therapeutic or nightly aspiration revealed free acid.

---

*From the Medical and Surgical Divisions of the Earl Clinic and the Medical Service of Ancker Hospital, St. Paul, Minnesota.

The very high acid values in this series were usually in duodenal rather than gastric ulcers, and many of the gastric ulcers had normal or low free acidity.

Emery and Monroe[4] in a review of 556 cases of peptic ulcer also reported hyperacidity in 75 per cent and hypoacidity in 9 per cent. They state that patients having symptoms over 20 years had no higher acidity than patients with recent ulcers.

There have been many cases reported in the literature of peptic ulcer in persons with an achlorhydria. However, the number of such cases is not as great as one would be led to suppose, for various careful investigators have shown most of them to be only apparent achlorhydria and to have been incompletely analyzed. Emery and Monroe[4] in their series found ten cases of ulcer with no free acid reported after an Ewald or a fractional test meal. Of these, one had pernicious anemia and an X-ray diagnosis of ulcer, but no symptoms of ulcer. Several others showed free acid after a meal or a therapeutic aspiration, and others had a very high total acid. They state that "there is no proof that true achylia gastrica occurred in any uncomplicated case in this series." Eusterman[5] in 1921 described two cases of anacidity following gastro-enterostomy for ulcer where free acid had been present before the operations. In one case, even therapeutic aspirations and Riegel meals yielded no free acid. Food and alkalies relieved the pain, however. In neither case was histamine used as a stimulus. Palmer[6] has presented a most careful résumé of the literature on achlorhydria and ulcer and has analyzed critically the various cases reported. Several of these were not bona fide cases of ulcer for they died of carcinoma metastases three to five years later. He states that with one exception (Eusterman's case, cited above) these are all unproved achlorhydrias for they are so named on the basis of only one Ewald or Boas meal or a fractional Ewald or Boas meal. Histamine tests and therapeutic aspirations were not tried. He mentions eighteen cases at the Presbyterian Hospital in Chicago where the free acid varied from 0 to 70 points on repeated Ewald tests, which emphasizes the necessity for more than one test meal if no free acid is found. Several of his patients who had no free acid with a fractional test later showed normal values with an Ewald. He analyzed the records of 1,469 ulcer patients at this same hospital and found only seven who never showed any free acid at any time. Four of these were ruled out because only one test meal had been used. Another was later diagnosed as gastric lues at Rochester and proved so at operation by Dean Lewis. Another was ruled out for lack of proof of ulcer (gastro-enterostomy and gastric resection had changed the normal physiology), and the seventh case was found at necropsy to have been that of a healed ulcer, with symptoms due to other causes. Palmer also criticizes a few more cases with which he was familiar from the Mayo Clinic and from the Cook County Hospital, and finds two of these suggestive but not proved cases of achlorhydria. The only case in the literature where test meals and therapeutic aspirations for benign ulcer failed to show free acid is that reported by Eusterman.[5]

When one stops to consider the mechanisms which control the values of gastric acidity in ulcer one naturally thinks of the effect of the obstruction at the pylorus or in the duodenum and its influence in inducing hypersecretion. This undoubtedly is an important factor, but even of more importance are the interesting recent observations of Elman[7] and of Olch[8] on the regulation of gastric acidity by duodenal regurgitation. These workers have shown experimentally that the pancreatic juice normally regurgitates into the stomach and thereby neutralizes gastric acidity. If this secretion (pancreatic) is diverted to the exterior of the animal, gastric acid values mount materially and hydrochloric acid meals put into the stomach are neutralized much more slowly, thus delaying emptying of the stomach. Acid solutions injected into the stomach of these animals provoke an intense increase in pancreatic secretion (thereby normally helping to neutralize the acid by regurgitation). Elman[7] has shown that bile cannot aid this neutralization for it is actually acid in reaction, rather than alkaline, as was formerly assumed. Elman and Rowlette[9] have further shown that experimental division of the pyloric sphincter (as in the Rammstedt operation on infants and the Deaver and Judd operations for pyloric stenosis in adults) leads to persistent lowering of gastric acidity as measured by an augmented neutralization of an "acid test-meal." This, they believe, justifies the conception of the "pyloric control of gastric acidity" rather than unqualified acid control of the pylorus. Disease of the pancreas prevents the regurgitation of alkaline fluids which would be allowed by this sphincter excision. Carcinoma of the stomach often allows rapid regurgitation of pancreatic fluid, thus lowering the gastric acidity, due to a mechanical splinting of the walls of the stomach by the cancerous tissue. This mechanical splinting may likewise slow the emptying time of these stomachs, which the lowered acidity would naturally have tended to accelerate. These observations are further of clinical importance for they help to explain why duodenal ulcers usually have higher gastric acid values than do gastric ulcers (unless the latter are near the sphincter), for this regurgitation of pancreatic juice is lessened by the duodenal narrowing. They also explain why such good results in the healing of ulcer following the making of a large stoma, as in gastric resection, pyloroplasty, or gastro-enterostomy. Many cases of hypoacidity and anacidity undoubtedly are due to rapid regurgitation of pancreatic fluid, which leads to a rapid decrease in gastric acidity, and hence to a more speedy emptying of the stomach.

If ulcers do occur in the absence of free acid (and to date it is questionable whether more than one case of this type in the literature is actually proved), what is the mechanism producing ulcer pain? There is no doubt that in many cases this pain is peristaltic in nature. Eusterman[5] in his case noted with a kymograph the peristaltic nature of the ulcer pain, yet aspiration of the stomach at the time of this pain gave no free acid. Smith, Paul and Fowler[10] have shown that the epigastric distress associated with an irritable colon is due to an increase in gastric tone and peristalsis, and in ulcer patients have produced their typical distress by inflation of the colon with air. This distress was proved to be due to increased gastric tone and peristalsis. However, in the majority of ulcer patients, it cannot be denied that the cause of their pain is an accumulation of free hydrochloric acid. This of course acts as an irritant and undoubtedly alters gastric tone and peristalsis. Palmer,[11] in another remarkable series of observations at Cook County Hospital, found that free acid is the usual irritant which causes ulcer distress. He produced the typical ulcer pain in ulcer patients by injections into one patient's stomach of gastric contents aspirated from another ulcer patient having pain, and by reinjection of gastric content into the stomach of a patient in whom its aspiration had brought relief. Such distress was not caused by injection of acid gastric contents into normal stomachs. Hydrochloric acid, sulphuric acid, acetic acid, and even sodium hydroxide were injected into the stomachs of ulcer patients and the typical pain produced. Neutralization or removal of these irritants relieved the pain. He found that in many patients with gastric carcinoma the typical distress was initiated and relieved in the same manner. He found no evidence of hyperesthesia of the normal gastric mucosa or of pain as the result of hyperchlorhydria with an intact gastric or duodenal mucosa. In a large series of ulcer patients at the Cook County Hospital in Chicago he found that spontaneous ulcer pain without free acid in the gastric content removed at the time of distress has been seen only once and that in a patient with a very sensitive pain-producing mechansim. To prove the value of neutralizing free acid the same author[12] later compared the value of treatment of two groups of ulcer patients at Cook County Hospital—one with hourly milk and cream and beef tea feedings, and one with hourly milk and cream feedings and alkalies in addition. Neutralization of the free acid by alkalies, used in conjunction with the hourly milk and cream feedings, definitely favored the healing process. This was indicated both by the earlier disappearance of spontaneous pain and by the earlier disappearance of sensitivity to injections of free hydrochloric acid. The recent attempt to substitute mucin for the alkalies in ulcer management, as reported by Fogelson,[13] further bears out the importance of free acid in ulcer management. This is still in an experimental stage but apparently may be a very useful measure. We have had no experience with its use.

Because of its bearing on the two case reports submitted below, the writers wish to digress somewhat and briefly consider the present-day views on the relationship of gastric ulcer to gastric carcinoma. Surely the finding of low gastric acid values with a gastric lesion in a patient who once had a high free acid and an ulcer demands investigation. However, as will be shown below, such a finding does not necessarily have much weight in deciding that a lesion is a malignant ulcer. Authorities are rapidly abandoning the still very prevalent idea that gastric ulcers are potential carcinomas and therefore are not to be treated by medical management. Cole[14] quotes Mayo as once making the statement that gastric ulcers over 2 cm. in diameter are malignant in 68 per cent of the cases. Cole points out that these large ulcers form only 10 per cent of all gastric ulcers. Therefore on Mayo's figures, 6.8 per cent of gastric ulcers are carcinomatous. Cole states that 6 per cent of gastric ulcers are or become malignant. He feels that repeated X-ray examinations of a gastric ulcer on treatment, at bed rest, are as decisive in ruling out carcinoma as are palpation by the surgeon at operation or even the microscopic examination of the tissue. Warthin in an address made in Minneapolis in 1929 emphasized the impression that carcinoma of the stomach is no more prevalent with or following gastric ulcer than it is in the general population not having ulcer. Emery[4] in his series (quoted previously) found that only 4.4 per cent of his gastric ulcer patients developed carcinoma after an average follow-up period of four and one-half years. The average duration of symptoms in these patients had been nine years, thus giving a total average observation period of thirteen and one-half years. Brown[3] in his report of 1,224 cases of ulcer had seventy-seven gastric ulcer patients. Of these, nine had died and in eight the cause of death was known. Only one died of carcinoma of the stomach. Bockus in discussing this report[3] stated that his experience as concerned the questionable relationship of gastric ulcer to gastric carcinoma was the same as that of Brown.

CASE REPORTS

Case 1.—C. A. D., a minister, aged sixty-three years, was first seen at the Earl Clinic by one of us (G. E.) in October, 1927, with the complaints of loss of strength and vitality, sleeplessness, loss of appetite, and nervousness. No nausea or vomiting had occurred. His family history and previous medical and surgical histories were irrelevant. The physical examination is recorded as showing normal pupillary and patellar reflexes, a soft systolic murmur at the apex which was not transmitted, and essentially normal lung findings. There was slight tenderness elicited in the gallbladder region. The abdomen was mildly distended. Some varicose veins of the left leg were noted. Laboratory reports gave his hemoglobin as 74 per cent, urine normal, temperature normal, pulse 78, blood pressure 112/78, and his weight 123. An Ewald test meal at 1 hour showed free acid 0, total acid 10. An X-ray of the stomach revealed a normal stomach with no retention of the six hour barium meal, and a large saccular duodenum with a deformity very suggestive of duodenal ulcer. There was retraction laterally of the second portion of the duodenum suggesting galbladder adhesions. The tonsils were chronically infected and were removed. The other treatment advised was a frequent feeding schedule, including liberal amounts of milk, cod liver oil, and olive oil as tolerated. He was given dilute hydrochloric acid and essence of pepsin.

The patient was not seen again until April 4, 1931. Meanwhile he had been examined at the Mayo Clinic in September, 1929. There also a duodenal deformity was found on X-ray. His gastric analysis (fractional probably) showed a free acid of 12, with a total acid of 20 to 32. It was felt at that Clinic that the patient's symptoms were only in part, if at all, caused by an active ulcer, and that worry and care were responsible for his symptoms. He was advised to follow a bland, high-vitamin, high-caloric, anti-constipation diet and was given belladonna, bromides and charcoal after meals. Calcium carbonate was to be used one hour after each meal.

When seen here in April, 1931, he stated that his symptoms were about the same as they had been in 1927. His distress was a dull ache near the navel at times, but usually a severe bloating and sense of heaviness in the epigastrium. This was never present before breakfast, but might precede the other meals and if so was aggravated by food taking. It might originate one to two hours after meals or at times immediately after meals, always disappearing if he could belch. No night pain. No vomiting nor acute colic nor jaundice. For the past week on the advice of his family physician he had been on an hourly alternation of milk and alkalies with considerable relief. His bowels had been functioning normally. No tarry stools. His appetite was poor. His strength had been poor, especially since an attack of "flu" five months previously. He had eaten no meat for three or four months. Worry always aggravated his distress.

The physical examination revealed a rather undernourished white male of 67, weighing 116 pounds. Pupillary and other reflexes were normal. Heart and lungs and thyroid appeared normal. Tenderness was present to a moderate degree in the mid-epigastrium and very slight rigidity of the upper right rectus muscle was noted. No edema of the ankles was seen. Rectal examination yielded nothing of importance.

Laboratory Data: Hemoglobin 82 per cent., R. B. C. 3,940,000, W. B. C. 8,200. Urine showed 1 plus albumin, no sugar, occasional white cells, an occasional granular cast. Temperature 97.2, pulse 90. Blood pressure 108/75. A differential blood count was normal. The smear showed no changes of a pernicious anemia type. A one-hour Ewald yielded no returns, so the test was repeated and aspiration done at thirty minutes. This showed free acid 0. Total acid could not be titrated due to the small volume obtained. A stool specimen contained no occult blood.

The patient had to go to Chicago for about ten days before the examination was complete. He was given belladonna and bromide for an assumed spastic colon, and the usual spastic constipation diet instructions. He was also told to use 30 drops of dilute HCl with each meal and a half hour after meals.

On his return he stated that he had felt fine on this management. Another Ewald was done. At one hour the free acid was 0, total acid 9 (25 c.c. of material aspirated). A trace of occult blood was detected in this specimen. Two stools both showed a small amount of occult blood. A fractional gastric analysis was done after injecting 0.6 mgm. of histamine. The results of this in terms of points of free acid at 15, 30, 45, and 60 minutes respectively were: a trace, 13, 15, 16 points. Occult blood was very prominent in these specimens. The patient had no bleeding from the gums, but possibly a small amount from hemorrhoids. A sigmoidoscopic examination revealed no pathology. A few days later four stools showed no occult blood.

X-rays: An X-ray of the gallbladder by the oral Graham-Cole method gave a normal picture. At fluoroscopy of the stomach, Dr. J. R. Aurelius detected, high on the lesser curvature of the stomach at the junction of the upper and middle thirds on the anterior wall, a fleck, 0.5 cm. in diameter, of a small penetrating gastric ulcer. Very slight induration was indicated and very little distortion of the rugæ. No spasm nor hyperperistalsis was noted. The old duodenal deformity was again seen but no evidence of an active ulcer was suggested there. Re-ray of the stomach two days later confirmed this finding. It was depicted on one of the films taken. A colon X-ray was negative for pathology. Marked hypertrophic arthritis of the lumbar spine was seen on these films.

After careful consideration of the various aspects of this case, an operation and resection of this lesion was advised and done by one of us (G. E.) on May 8, 1931. At operation a small, indurated, partially healed ulcer with a shallow crater, 4 mm. in diameter, and with a zone of induration of 1.5 cm. diameter was found at the site shown in the X-ray. No evidence of metastases in the glands or liver was found. Simple excision of this ulcer was done. The patient made an uneventful recovery except for some painful induration in the thighs, produced by the hypodermoclysis, which prolonged his convalescence. He left the hospital in five weeks and three days. To the present date he has been on a Sippy medical management for ulcer as a post-operative measure. A recent letter from him reveals a satisfactory result. The microscopic sections of this ulcer gave no evidence of malignancy.

Case 2.—P. S., aged forty-eight years, white male, whose occupation was dishwashing, entered Ancker hospital April 26, 1931. Seven years previous he had had an operation for ulcer, the nature of which could not be ascertained. The patient apparently had symptoms of an acute perforation and thinks a gastro-enterostomy was done. His present symptoms developed three years before and consisted of localized epigastric pain just to the left of the mid-line. This pain was relieved by food, soda (1 teaspoonful) or vomiting. For a month prior to admission he had been vomiting about one hour after meals. Some dark blood had been seen in the vomitus. Tarry stools had been noted for one week. Some night pain was present till about 2 a. m. He had lost 15 pounds in the past month.

Physical examination revealed nothing of importance in the head, neck, or thorax except a few coarse moist râles near the hilus of each lung posteriorly. These disappeared after coughing. His abdomen had an upper right rectus operative scar. Very slight epigastric tenderness was present.

The stomach was inflated with carbon dioxide (tartaric acid and soda) and no visible peristaltic waves were seen during a 20 minute period.

Laboratory Data: Blood pressure 100/70. Hemoglobin 94 per cent. Red blood cell count 4,930,000. White blood cell count 7,250. A differential count and smear were normal. The blood Wassermann was negative. A one-hour Ewald meal yielded no free hydrochloric acid and a total acid of 9. The volume of fluid aspirated was 200 c.c. No occult blood was present. One stool showed occult blood but many successive stools were free of occult blood. A histamine injection with a fractional gastric analysis yielded a good output of free hydrochloric acid (up to 32 points of free acid and 59 of total) in a one-hour period.

X-ray: Fluoroscopy of the stomach by Dr. J. R. Aurelius revealed a large penetrating gastric ulcer (3 × 2 cm.) on the lesser curvature and posterior wall of the middle third. There was also a duodenal deformity with spasm and a suggestion of a fleck ulcer being present. No evidence of a gastro-enterostomy was seen.

The patient was placed on a careful Sippy management with test aspirations periodically one-half hour after a dose of alkali and also at bedtime to be sure of effective neutralization of acidity and of emptying of the stomach. One such aspiration of the stomach one-half hour after a dose of alkali revealed free acid of 14 and total acid of 84. The hourly dose of calcium carbonate was promptly increased and successive aspirations yielded no free acid.

X-ray one month later (fluoroscopy and films) revealed, "now only the slightest evidence of the previous ulcer on the lesser curvature, showing marked improvement since the last examination. The duodenal cap remains deformed. There is now no evidence of ulcer crater and only slight spasm present in the cap. There is, however, a rather definite point of tenderness over the duodenal cap" (report again by Dr. J. R. Aurelius).

The patient was discharged from the hospital June 6, 1931, to carry on ambulatory medical management for his two ulcers, and to report back to the out-patient department of Ancker Hospital.

DISCUSSION

The advisability of resorting to surgery in Case 1 may be questioned, since medical treatment of gastric ulcer is now being chosen by the most careful authorities in preference to surgery, particularly when the ulcer is not adjacent to the outlet of the stomach. Our main reason for advising surgery was that our patient was a man of 67 years with a small gastric lesion which had developed since he was last seen here in 1927, in the face of a very low gastric acidity, approaching an achlorhydria. We felt that his symptoms were entirely due to a spastic colon which he had obviously possessed four years previously and these symptoms were not changed by the development of the ulcer. Therefore, a symptomless gastric lesion appearing in the face of a known very low acidity was our chief reason for advising operation and excision of the ulcer. It was felt that if it was carcinoma an operative cure was assured. We were not influenced by a fear that this ulcer might develop into a carcinoma (for the lack of a good basis for this idea has already been pointed out), but we believed that this might actually be a carcinoma, due to the circumstances surrounding its development. The occult blood reactions in the stool were suggestive of carcinoma at first but later the stools were free of blood. Another reason for advising surgery was that this stomach was of a long, vertical fishhook type, with rapid emptying (so much so that even in 30 minutes an Ewald meal was recovered only once in three trials), and the ulcer was high up on the lesser curvature. We felt that in the absence of a high acidity and with the rapid emptying the usual form of medical treatment, which has as its basis neutralization of free acid, was unlikely to be highly successful for our fluoroscopy showed the impossibility of keeping the milk or alkalies in contact with this ulcer.

In passing, we wish to emphasize the technic used by Dr. Aurelius in finding this very insignificant fleck by fluoroscopy. There is no question that if, as usually is done by X-ray men, the stomach had been filled with barium, this lesion would have been missed, but by having the patient take only one swallow of barium and watching it pass over the rugæ slowly, combined with careful palpation, Dr. Aurelius detected this tiny fleck, about 0.5 cm. in diameter, on the anterior wall just off the lesser curvature at the junction of the upper and middle thirds of the stomach.

Case 2 illustrates, as does Case 1, the value of histamine in eliciting a flow of free acid when Ewald meals showed an achlorhydria. Comfort and Osterberg[15] in a recent report from the Mayo Clinic question the advantages of histamine over an Ewald or fractional test, except in cases where a gastro-enterostomy or gastric resection allows alkaline regurgitated fluids to mask the output of free acid. They state that the advantages of histamine over the Ewald are not great enough to warrant the adoption of stimulation by histamine as a routine procedure. These authors also cite cases of gastric carcinoma having as great a concentration and volume of free hydrochloric acid as those obtained in duodenal ulcer. In our experience we have found histamine stimulation to be an invaluable aid in separating apparent from true achlorhydria. The dose used is 0.1 mgm. of histamine subcutaneously for each 10 kilos of body weight of the patient.

Another valuable aid in the analysis of apparent achlorhydria in ulcer patients is the therapeutic aspiration, *i.e.,* aspiration of gastric contents at a time when the patient complains of pain. If this had been done more frequently, the literature relating to achlorhydria in ulcer patients would be very nearly negligible. Our second patient who showed no free acid with an Ewald meal not only had a good output of free acid with histamine stimulation but also showed free acid in good concentration in one test aspiration (one half hour after a dose of alkali) which aspirations are routine on our service in ulcer cases. Aspiration for free acid three hours after a Riegel meal or four hours after an ordinary meal will usually show a high acid concentration in ulcer patients though the test meals show achlorhydria.

It must be emphasized that gastric contents containing food must be titrated immediately and cannot be allowed to stand overnight if the true free acid values are desired. Otherwise the free acid is changed to combined acid.

Finally, the importance of routine stool examinations for occult blood is not to be overlooked. Finding occult blood, of course, may be compatible with either ulcer or carcinoma, but the absence of occult blood, using the benzidine test, in repeated stool examinations, rules out the presence of carcinoma with as great an accuracy as is offered by X-ray. In our Case 1 both the X-ray and the stool examinations pointed to the absence of carcinoma, yet we feared it because of the hypochlorhydria which was known to have been present for at least four years. Our fears were unfounded. In our Case 2 the absence of occult blood in repeated stool examinations absolutely confirmed the X-ray diagnosis that this large lesion on the lesser curvature was a benign penetrating ulcer. Any malignant lesion of that size will continue to show 4 plus occult blood reactions in the stools.

The rapid disappearance of the huge penetrating lesion as shown by repeated X-ray studies in Case 2 is typical of the very satisfactory results of medical treatment of gastric ulcers in general, if uncomplicated by pyloric obstruction.

SUMMARY

Literature is cited to show the confusion that exists regarding the coincidence of peptic ulcer and achlorhydria and to prove that, with only one or two exceptions, cases reported to show such a coincidence have been insufficiently studied and are unproved. Two case reports are included showing gastric ulcers with apparent achlorhydria but in which more careful study revealed an adequate free acid concentration compatible with peptic ulcer. The methods available in the study of gastric acidity in ulcer are discussed. The importance of routine stool examinations in the diagnosis of ulcer and gastric carcinoma is emphasized.

CONCLUSIONS

1. An active peptic ulcer in the presence of true gastric achlorhydria is so rare as to be negligible.
2. Histamine stimulation of gastric secretion should always be tried before diagnosing achlorhydria, or even hypochlorhydria, where peptic ulcer is suspected. In our experience it has caused free acid to appear frequently where the ordinary test meals showed achlorhydria.
3. Aspirations of the stomach at the time of suspected ulcer distress, or four hours after a heavy meal or Riegel meal, should be resorted to if an Ewald shows no free acid. Failure to use all of these useful procedures is responsible for nearly all the reported and erroneous diagnoses of achlorhydria associated with peptic ulcer.

PEPTIC ULCER: A REVIEW OF RECENT OPINIONS OF ETIOLOGY AND TREATMENT*

Albert M. Snell, M.D.
Rochester, Minnesota

MANY American clinicians are inclined to subscribe to the theory that the typical callous peptic ulcer forms from acute lesions or erosions, which are rendered chronic by their position and the action of the gastric juice. Numerous ideas with regard to the formation of acute lesions have been advanced; it has been suggested that they may be of vascular, traumatic, or infectious origin. The vascular theory, first suggested by Virchow, is supported by the work of numerous investgators who have demonstrated lesions in the gastric arteries. More recently von Bergmann has suggested that spasmodic contraction of the afferent vessels of the stomach may be responsible for localized destruction of the mucosa.

The researches of Ivy,[8,14] McCann and other investigators indicate the relation of trauma to the development and healing of ulcer. Undoubtedly, the gastric and duodenal mucosa is often injured from coarse particles of food, hot or cold beverages, vomiting, external pressure and chemical irritants. Such lesions are probably not confined to any one area in the stomach; from what is known of gastric mechanics, they should be most common along the lesser curvature, in the pyloric antrum, and in the duodenum, regions of the stomach which constitute the so-called Magenstrasse or gastric groove.

Many infectious processes have been known to cause acute gastric ulceration or erosion, and it is a matter of general clinical observation that reactivation of duodenal ulcer often follows infection of the upper part of the respiratory tract or interference with oral foci. The work of Rosenow, in 1913, called attention to the significance of distant foci of infection. Streptococci isolated from such foci produced gastric lesions ranging from hemorrhagic areas to superficial erosions in experimental animals. Such lesions may well furnish the original mucosal defect from which a chronic ulcer is formed by traumatic, chemical, and constitutional factors.

It is probable that acute gastric or duodenal lesions of one kind or another must be fairly common, and that they usually heal without producing symptoms. The knowledge of what determines the course of such lesions, and why some heal whereas others become chronic and intractable, would probably settle many disputed questions with regard to ulcer. The position of the lesions is, of course, significant; those which lie in the gastric groove are subjected to additional chemical or mechnical trauma and may readily become chronic. This "mechanical functional hypothesis" for which we are indebted to Bolton and to Aschoff, cannot be overlooked in any consideration of the etiology of ulcer.

Constitutional factors, perhaps, deserve the next consideration. It is generally recognized that such conditions as an ulcer diathesis and ulcer disposition exist, but on what factors these are based has not been explained. Draper's data suggested a certain similarity in anthropometric measurements in cases of ulcer, as contrasted, for example, with cases of cholecystitis. Various writers have suggested a vagotonic constitution as a prerequisite to the development of ulcer; others have suggested a sort of spasmophilic diathesis as a basis. Winkelstein advanced the idea that patients with peptic ulcer are more sensitive to a variety of physical and pharmacologic stimuli than normal persons. Hypotheses of the constitutional basis of ulcer presuppose to a greater or less extent abnormal reactivity of gastric secretion and motility to psychic and emotional stimuli as well as to the stimulus of ingested food. Clinically there is much to support this view, since reactivation of symptoms of ulcer under emotional stress is common. Recent studies on gastric innervation are of interest in this connection, since any constitutional tendency to ulcer might well be associated with functional abnormalities of nervous connections.

---

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the Northern Minnesota Medical Association, Hibbing, Minnesota, September 14, 1931.

Hartzell found that after section of the vagi of dogs there was a reduction in the amount and the acidity of gastric secretion, and that the psychic variations in secretion were practically abolished. After section of the splanchnic nerves, Vanzant found little change in the reaction of gastric secretion to various stimuli; she also checked data concerning Hartzell's original animals and found that two years after vagotomy the normal secretory activity was restored. Animals with completely denervated stomachs also exhibited an essentially normal response, although the flow of gastric juice after a meal of meat or an injection of histamine was distinctly slower and of a less magnitude than before operation. Such results can only be interpreted to show that the stomach has a high degree of automaticity in respect to both its motor and secretory functions, and that its nerve connections do not control all of the various processes which may underlie gastroduodenal ulceration.

Chemical factors in the production of ulcer have been regarded as of great significance since the corrosive action of gastric juice was first demonstrated; in fact, the presence of free hydrochloric acid in gastric secretion is a sort of *sine qua non* in ulcer. It has been generally held that secretions of the stomach have no effect on normal gastric or duodenal mucosa if the blood supply is adequate. The recent experiments of Overgaard, who was able to produce pyloric gastritis with superficial erosions by giving repeated injections of histamine to fasting dogs, bring this older view into question. However, many normal persons have a more or less continuous hyperacid secretion, but do not have demonstrable ulcer. It has been stated that there is a protective mechanism which may fail and thereby favor the development of ulcer, but definite proof of this is not available. Mucin, which is one of the recognized physiologic antacid substances, is likely to be present in gastric secretion roughly in an inverse proportion to the height of acidity. Another protective factor, the normal alkalinity of the duodenal secretions, may be still more essential. Mann and Williamson, by diverting the biliary and pancreatic secretions into the ileum and connecting the jejunum directly with the stomach, produced chronic indurated jejunal ulcers with great uniformity. Bollman noted similar ulcers in experimental obstructive jaundice. Apparently the neutralization of gastric acid by the duodenal juices, bile and mucin is a protective mechanism which usually prevents corrosive action. Why such protective mechanism fails in the presence of ulcer is still unexplained.

American views on the genesis of ulcer have been well stated by Crohn; his statement may be paraphrased here. He assumes that ulcer occurs in young subjects of vagotonic habitus, whose gastroduodenal mucosa is rendered vulnerable by vascular spasm, infection, or trauma, and has been digested by the corrosive action of the gastric juice. If the erosion occurs in the gastric groove it is rendered chronic by its situation and consequent exposure to mechanical and chemical irritation. Secondary factors such as vascular occlusion, focal infection, and motor dysfunction then tend to perpetuate the lesion. In chronic ulcer, motor disturbances are undoubtedly of the greatest significance. Pyloric obstruction, even if temporary, tends to delay the healing of experimental peptic ulcers; pylorospasm is probably responsible for most of the daily pain and discomfort of the patient with ulcer; and, finally, all successful surgical procedures for the cure of ulcer involve either the division or removal of the pyloric sphincter, or else render it functionally useless. The pylorus forms the mixing valve arrangement by which the reaction of the gastric content is regulated in the region of the stomach most subject to ulceration. More information regarding the pathologic physiology of this important structure would furnish many additional clues to the cause of ulcer and means whereby it might be cured.

At present, the hypothesis of German observers on the etiology and nature of ulcer forms a decided contrast to those held in this country. Constitutional factors are of course regarded as important, and the "mechanical functional hypothesis" is given credence. Views on the relation of gastritis and duodenitis to ulcer, however, exert the greatest influence on ideas of treatment. Konjetzny and others assert that all gastroduodenal ulceration is accompanied by gastritis and duodenitis which may take the form of submucosal infiltration, simple erosion, or superficial, but nevertheless chronic, ulceration. German pathologists and surgeons have presented a great deal of evidence in support of this view, and their claims cannot be easily dismissed. During a recent visit to German surgical clinics, I had the opportunity of seeing a large number of specimens of resected stomachs. In most of them gastritis, duodenitis, and multiple superficial ulcerations were definitely present; in other specimens, the diffuse inflammatory process was less definite. American observers have not been impressed by the relation of gastritis to ulcer, although it is generally agreed that ulceration in either stomach or duodenum may be and often is accompanied by local inflammation. Judd, Nagel and Rivers described the clinical syndrome and the pathologic pictures of duodenitis, gastritis, and gastrojejunitis. Unfortunately, the syndrome of associated ulcer and gastritis is difficult to establish. Most of the evidence now available has been observed in pathologic specimens, and at operation. There is no characteristic change in secretory activity in gastritis. Roentgen-ray diagnosis of the condition is extremely difficult and only gastroscopy can establish the diagnosis unless operation is performed. Gastritis is probably worthy of greater attention than it has hitherto received, particularly from the standpoint of diagnosis in the intact individual. In Germany students of the subject have a distinct advantage because of the frequent use of the gastroscope and the practice of doing extensive gastric resections for all types of peptic ulceration, which furnishes much fresh pathologic material for study. Those who are advocates of the theory of gastritis naturally favor resection as essential to cure. It is obvious that any marked degree of this condition precludes to some extent successful medical treatment and also favors the development of recurrent or anastomotic ulceration when conservative surgical measures are practiced.

TREATMENT

In the United States the value of the Sippy treatment or some modification of it in selected cases, particularly in those in which ulcers have recently formed, is generally conceded. Hospitalization of the patient is necessary, and rigid control of the gastric acidity must be carried out if the best results are to be obtained. If lesions are chronic, treatment, even under the best possible conditions, will not yield as high a percentage of permanent medical cures as one might wish. Many patients with chronic duodenal ulcer are unwilling to submit to rigid medical treatment, and some ambulatory form of treatment must be devised. Curiously enough, ambulatory treatment has a fairly good record in the treatment of peptic ulcer. Blackford and Bowers have shown that with ambulatory treatment the end-results are practically as good as if patients have had the benefit of thorough hospital treatment. Recently, some new forms of medical treatment have been suggested. The work of Fogelson on the use of gastric mucin has attracted much attention, but it is still too early to evaluate results. Symptomatic relief has been obtained in many cases, but in some cases of long standing the results have been less satisfactory. Specific vaccines have been employed with variable results, but in general this type of treatment is not greatly favored in the United States. The use of nonspecific vaccines, which was originally advocated in Germany, seems to have been largely abandoned by clinicans there. The method of treatment has been used at The Mayo Clinic in the treatment of recurrent ulcer with somewhat disappointing results. Often gastric acidity is reduced for a matter of twenty-four hours following the administration of typhoid vaccine, and during this period there may be definite relief of pain. Only in the occasional case have the results been sufficiently permanent to encourage further trial of the treatment.

American statistics as to the percentage of medical cures of duodenal ulcer vary greatly, as do percentages on mortality in cases in which operation is not performed. Cures have been claimed in 80 per cent of cases; more conservative figures are as low as 20 per cent. The results to be expected from medical treatment vary greatly with age and sex, duration of the ulcer, and the patient's economic condition. The asserted permanency of the cure depends to a great extent on the length of time a given case is followed. Symptomatic relief is easy to obtain, but permanent and complete cure is an entirely different matter. It must not be forgotten that spontaneous cures do occur. According to Stewart, about 12 per cent of subjects coming to necropsy present evidence of past or present ulceration of the stomach; Robertson and Hargis' figures are considerably higher (20 per cent). Symptoms of ulcer are not present in all of these cases; in many, only brief atypical periods of indigestion are known to have occurred. Usually only the most cursory treatment has been given, nevertheless at necropsy a considerable percentage of the lesions is completely healed. These facts must be considered in the evaluation of any form of treatment.

Medical treatment of duodenal ulcer in European clinics is probably not practiced as extensively as in this country; economic difficulties are the principal objection to treatment of this type. Several popular forms of medical treatment are practiced in Germany, such as the Lenhartz diet with or without alkali; various types of bland food given with large amounts of dextrose and belladonna to the point of tolerance, and the Sippy treatment or some modification of it. In some central European clinics a sugar cure is used, on the basis that patients with ulcer suffer from chronic acidosis, as shown by increased tolerance to alkalis. Insulin was originally used in this treatment, but at present large doses of sugar by mouth are employed to compel the patient to manufacture his own insulin. In one German clinic I visited jejunal feeding by means of a special tube was the method of choice. This involves retention of the tube for several weeks, and in spite of the incidental discomfort good temporary results are obtained. Many German physicians are rather pessimistic as to the permanence of the medical cure of ulcer, and I found it difficult to obtain entirely satisfactory data as to the end-results. A number of the internists took the view that it is necessary to produce radical change in gastric physiologic processes before permanent cure can be expected.

Surgical treatment of duodenal ulcer in America and in the British Isles has been confined largely to gastro-enterostomy or some form of pyloroplasty; gastrectomy is reserved as a rule for gastric ulcer or carcinoma. Statistics on the value of these conservative procedures collected over a period of years indicate that good results are obtained in approximately 90 per cent of cases. The surgical mortality varies with the experience of the operator, but in skilled hands it may be as low as 1 per cent. The rate of recurrence does not seem to be particularly high; the most accurate figures available indicate that it does not exceed 5 per cent. Gastrectomy has been advocated by certain groups of surgeons in this country largely as a means of avoiding recurrent or anastomotic ulcers. In one American institution in which partial gastrectomy for duodenal ulcer is widely practiced, associated gastritis and duodenitis is said to be common.

In many of the German, Austrian, and Hungarian clinics, and in one large clinic in Paris, gastrectomy is almost universally employed in the treatment of both duodenal and gastric ulcer. German surgeons in general state that the rate of recurrence of ulcer after conservative operation (gastro-enterostomy or pyloroplasty) varies between 10 and 35 per cent. This high rate may be due to the gastritis, duodenitis, and multiple ulcerations which are observed so frequently in these clinics; it may also be due to delayed surgical intervention. The average surgical mortality for subtotal gastrectomy is not less than 5 per cent; good permanent results are obtained in about 85 per cent of cases. The rate of recurrence of ulcer after subtotal gastrectomy is said to be about 1 per cent or less. However, the operation is not without drawbacks and some of its proponents admit that a fairly large group of patients appears to have a good deal of trouble in spite of extensive resection. Gastrogenic diarrhea, anemia, cholangeitis, and motor disturbances are the common causes of unsatisfactory results. Henning recently performed gastroscopy on a considerable number of patients who have continued to suffer with digestive disturbances following subtotal gastrectomy. He found that a high percentage of them had definite, visible gastritis which is persistent.

So far as the future of primary partial gastrectomy for duodenal ulcer in this country is concerned, it appears that it should be confined to individual cases in which marked diffuse gastroduodenitis or multiple ulcerations can be demonstrated. Unfortunately, such demonstration is not often possible except at the time of operation. If one were certain of detecting in advance the patient with a constitutional tendency to the formation of ulcer and therefore especially likely to recurrence, gastrectomy might be justifiable for this type also. It does not, however, seem entirely proper to use the admittedly high incidence of recurrence of ulcer in European clinics as an argument in favor of gastrectomy in this country, since there are probably pathologic variations as well as economic and dietary factors which may explain the variations observed.

SUMMARY

Many American students are inclined to regard gastroduodenal ulceration as the end-result of an acute lesion produced by trauma, infection, or vascular lesions, which has become chronic because of its position and the corrosive activity of the gastric juice. The process is regarded as essentially reversible and one which may be corrected by a proper dietary regimen, the control of gastric acidity, and removal of foci of infection, provided the psychic and environmental factors which may predispose to ulcer can also be regulated. In the intractable chronic case, in which economic and other handicaps and such complications as hemorrhage, obstruction, and penetration enter the picture, surgery, usually of a conservative type, is the procedure advocated.

In central European clinics, a high incidence of associated gastritis and duodenitis and a stated high rate of recurrence after conservative surgical procedures combine to make subtotal gastrectomy the preferred method of treatment. It is suggested that perhaps geographic, dietary, and environmental factors may be involved in these differences of opinion, and that a closer comparison of the pathologic changes of ulcer as it is observed in this country and in central Europe may help to reconcile the advocates of radical and conservative methods of treatment.

CONVULSIONS IN CHILDHOOD*

M. G. Peterman, M.D.
Milwaukee, Wisconsin

A CONVULSION is one of the most alarming symptoms which can occur to a child. To the parents it signifies an impending catastrophe and to the physician, unless he recognizes epilepsy, the symptom presents an acute problem for treatment and diagnosis. While a convulsion is usually not fatal, it always produces a certain amount of cerebral damage which lowers the threshold for subsequent attacks; therefore immediately succeeding the problem of the control of the acute attack comes the question of a differential diagnosis. Every effort must be made to determine the basic cause of the symptom, convulsive state, and to prevent a recurrence. In this paper a convulsion is interpreted as a series of involuntary contractions of a group or of several groups of muscles usually associated with a loss of consciousness or cerebral function.

I have made a study of 400 children who have been brought to the Milwaukee Children's Hospital in the past five years for the treatment of acute convulsions. The ages of the patients range from an hour to fifteen years. Many were brought in during or shortly after a convulsion. It will be realized that with the attendant excitement and confusion and the unavoidable delay the physician often arrives at the home or the patient at the hospital after the convulsion is over.

In each case every possible effort was made by clinical and laboratory examinations to make a diagnosis. This includes as complete a history as obtainable, a complete physical (and neurological) examination, examination of the fundi, urinalysis, spinal fluid examination, X-ray of the skull, and determinations of the blood Ca, P, N, blood culture, etc., somewhat in the respective sequence. Some patients were seen only once and for a short time, often making a diagnosis impossible.

On the basis of this study a classification of convulsions is presented according to age groups (Tables 1, 2, 3, 4). This classification has been found to be the most convenient for clinical purposes. It will be noted that the most common cause of convulsions in the newborn infants is cerebral injury (hemorrhage, congestion, or edema). The premature infant is most susceptible because of his soft bones, ununited sutures, widely open fontanel, and fragile vessels. Long labors, or rapid precipitate deliveries, breech deliveries, or instrumental deliveries are predisposing factors but often there is a history of a normal labor and delivery.

There is a period between the first few weeks of life and approximately eight months when convulsions are relatively infrequent. The explantation is obvious: the immediate results of birth injury are passed, tetany is not yet present, and the acute infectious diseases do not occur.

TABLE 1.—NEWBORN INFANTS AND FIRST MONTH

1. *Cerebral Injury.*
   - Hemorrhage.
     - Subtentorial
     - Subpial
     - Ventricular
   - Compression.
     - Congestion
     - Anemia
2. *Septicemia.*
   - Nasopharynx.
   - Umbilicus.
   - Skin Infections.
3. *Congenital Anomalies.*
   - Hydrocephalus.

TABLE 2.—FIRST TO EIGHTH MONTH

1. Residue of Birth Injury.
2. Septicemia, Onset Acute Infections.
3. Congenital Anomalies.
4. Toxic: Poisons, Terminal.

TABLE 3.—EIGHT TO THIRTY-SIX MONTHS

1. Spasmophilia or Tetany.
2. Septicemia, Including Onset of Acute Infections as Pneumonia, Meningitis, etc., and the Onset of the Acute Infectious Diseases.
3. Residue of Birth Injury.
   - Hydrocephalus.
   - Congenital Anomalies.
   - Syphilis.
   - Epilepsy.
   - Cerebral Hemorrhage.
   - Serous Meningitis.
   - Brain Tumor or Cyst.
   - Toxic: Intestinal Obstruction, etc.

---

*From the Department of Pediatrics, Marquette University, and The Milwaukee Children's Hospital. Read before the annual meeting of the Southern Minnesota Medical Association, Faribault, Minnesota, August 24, 1931.

TABLE 4.—THREE TO FOURTEEN YEARS

1. Residue of Birth Injury.
2. Septicemia Including Onset Infections and Infectious Diseases.
3. Epilepsy.
4. Spasmophilia.
5. Chronic Encephalitis, or Encephalitis or Meningitis Residue.
6. Brain Tumor or Cyst.
7. Hydrocephalus.
8. Toxic, etc.

The most common causes left are the residues of birth injury and the onset of acute infections or septicemia.

From eight to thirty-six months of age, spasmophilia dominates the picture as the cause of convulsions, closely followed in frequency by the onset of the acute infectious diseases. Tetany occurs in the rachitic infant usually in the spring and fall.

After three years the onset of acute infections and the infectious diseases are the important factors, followed by the residues of birth injury, epilepsy, etc.

Most convulsions are the immediate result of cerebral edema. This may not necessarily be expressed in an increase of the spinal fluid pressure. The fluid may be held bound in the brain cells. The convulsions of the acute septicemias and of epilepsy are usually associated with a polynuclear leukocytosis.

Treatment.—The immediate treatment of most convulsions is the treatment of cerebral edema.

Two to 6 ounces of a saturated solution (50 per cent) of magnesium sulphate should be given by mouth, if possible, or by rectum following an enema. A 10 per cent solution of glucose or of sodium chloride intravenously will produce the same hypertonic effect. For quicker action 5 to 20 c.c. of a 10 per cent solution of magnesium sulphate may be injected intravenously (slowly) or intramuscularly.

If the child is seen in acute convulsions in the home and facilities are limited, chloroform anesthesia offers a quick and effective method of treatment which is easily administered. Ether is a second choice.

TABLE 5.—TREATMENT OF CONVULSIONS

1. Protect Against Injury.
2. Chloroform or Ether Anesthesia.
3. Saturated Solution of 25 per cent Magnesium Sulphate, 4 ounces by Rectum or by Mouth; or and, 2 to 5 c.c. of 2 to 10 per cent Solution Intravenously, or 5 to 10 c.c. Intramuscularly.
4. Spinal Puncture If No Brain Tumor.
5. Chloral by Rectum.
6. Phenobarbital by Mouth or Soluble Barbituric Acid Preparations Hypodermically.
7. Treat Basic Disease.

Spinal fluid drainage is indicated as a therapeutic and diagnostic measure as soon as it can be done. A possible brain tumor, of course, demands caution in the withdrawal of fluid.

Sodium-phenobarbital and other new soluble barbituric acid compounds may be injected intramuscularly. Sodium amytal (Lilly's special preparation for intravenous injection) may be injected intravenously, 1.5 mg. per kilo body weight, if the child is quiet enough to permit it. This drug has been effective in two cases in which all of the above procedures were futile.

After the immediate treatment of the convulsion the basic disease should be given attention.

Conclusions.—The most important factor in a consideration of convulsions is the differential diagnosis. A convulsion is only a symptom and is usually due to cerebral edema. The immediate treatment of the convulsion is the treatment of cerebral edema.

NORMAL AND ABNORMAL MOTILITY SYNDROMES OF THE UPPER URINARY TRACT, WITH INDICATIONS FOR DRUG AND SYMPATHECTOMY THERAPY*

William P. Herbst, M.D.
Minneapolis

A LARGE proportion of medical investigation and effort in the field of the physiology of the kidney has heretofore been mostly confined to observations on the secretory function. Very recently investigations have delved into the dynamic or motility side of the renal and ureteral physiology and at present I feel we are just on the threshold of many valuable developments in this field.

When one considers that adequate drainage of the urinary tract is of such extreme importance in infections of the kidney, renal sufficiency and calculus formation, we must conclude that we have been rather lax in our investigation and observation along this line.

The influence of the central nervous system on the secretory function of the kidney has long been a subject of research endeavor. Claude Bernard, way back in 1859, observed that cutting the splanchnic nerves in the dog resulted in an increase in the amount of urine secreted by the kidney. Since that time there have been numerous reports of experimental work done in this field.

At present it is generally accepted that the secretory function of the kidney is controlled by the vasomotor action of the sympathetic nerves. We now know that the entire nerve supply to the kidney may be interrupted in either one or both kidneys in the human without any untoward effect. Not only is there no untoward effect, but we know that the volume of urine secreted is increased about 25 per cent, with a relative decrease in concentration and an actual increase in the total amount of solids secreted.

I mention this to relieve any anxiety about any damage to renal function resulting from renal sympathectomy which may be contemplated to relieve painful renal syndromes which will be described at greater length later on. Heretofore, patients with such conditions as renalgia or nephralgia, painful nephroptosis, and various painful conditions calling for plastic operations, have been operated upon with rather inaccurate theoretical indications.

This brings up the question of a recent aid in the way of investigation of the upper urinary tract physiology as regards the motility. Manges has visualized the renal pelvis fluoroscopically since 1912 mainly for the purpose of insuring satisfactory filling of the renal pelvis or ureter before taking pyeloureterograms. Recently a number of investigators have made further detailed observations by this method. Jona and Flecker last July reported some observations on the action of atropin, morphin, eserine, pituitrin and ergot on the motility of the renal pelvis and ureter by direct fluoroscopic observation. They found that atropin resulted in definite relaxation and distention of the renal pelvis even to the extent of producing pain, which pain in turn was relieved by the administration of eserine. They observed that morphin, eserine, pituitrin and ergot all definitely stimulated the motility.

Shortly after this Harris and Harris reported their observations on a series of 28 patients in whom they had done renal sympathectomy for painful abnormal renal motility syndromes, with 100 per cent satisfactory relief. They made their diagnosis of what they called renal sympatheticotonus by the fluoroscopic demonstration of spasm in any portion of the renal pelvis accompanied by delayed emptying time, reproduction of the pain by over-distention, and symptomatic relief of the pain by the administration of eserine. Of particular interest was their report of one case of chronic glomerular nephritis which was not doing well under medical management but definitely improved a year after renal sympathectomy on each kidney with a three months' interval between operations.

The above contributions have been the basis of the observations that I have made and which I am interested in reporting today.

Slides were shown illustrating (1) the nerve supply to the kidney with its anatomical relations in the region of the renal pedicle and pelvis; (2) the normal mechanism of the renal pelvis and ureter; (3) abnormal mechanisms of the renal pelvis and ureter; (4) urograms illustrating various abnormal motility syndromes. The treatment of these cases was discussed and the results of the administration of eserine and renal sympathectomy were described.

---

*Read before the annual meeting of the Southern Minnesota Medical Association, Faribault, Minnesota, August 24, 1931.

I feel very strongly that in the past countless patients with painful abnormal motility syndromes have gone on without relief because of our inability to recognize them by the means of urological investigations then at hand.

SUMMARY

1. We have available a method of observation of the motility of the upper urinary tract which should prove to be a fertile field for further useful and productive work.

2. Abnormal motility syndromes, corresponding to pylorospasm, cardiospasm, hypermotility of the stomach, spastic colon, and auricular fibrillation, will be recognized as definite entities occurring in the urinary tract.

3. The operation of nephropexy most likely is successful or unsuccessful in relieving the renal pain according to the degree to which the sympathetic nerve supply to the kidney is interfered with during the operation.

4. The satisfactory results in pain relief in much of the plastic work that is now being done upon the kidney I believe in many instances to be due to interference with the central nervous system control on the motility of the upper urinary tract.

5. Renal sympatheticotonus, as described by Harris and Harris, seems to be a well-defined entity which may be relieved by eserine or renal sympathectomy.

6. There have been a few cases of painful ureteral motility syndromes which have been relieved by nerve-stripping of the ureter, as reported by some recent writers.

7. The field of renal sympathectomy for certain nephritic conditions is merely mentioned as being a field for future observation and work.

8. Reflex anuria in a case of ureteral lithiasis had been relieved by injection of the splanchnic nerves by the method of Kappis.

MALIGNANT CONDITIONS IN RADIOACTIVE PERSONS

In 1925, Martland reported cases of anemia and of necrosis of the jaw in persons who had been employed in painting watch dials with paint made luminous by the addition of radium, mesothorium and radiothorium. During several years previous to 1924, 800 girls did such work in a New Jersey factory. The girls swallowed small amounts of radioactive paint day after day as a result of pointing the brushes with the lips. Some who had worked for one or more years developed necrosis of the jaw and anemia, from which, up to 1928, thirteen died. Now, however, another pathologic condition seems to have arisen among the employees who swallowed radioactive paint. Since 1928, rapidly growing osteogenic sarcomas have appeared in at least eight cases. In consideration of recent developments the high incidence of primary carcinoma of the lungs in the cobalt miners of Schneeberg and in the pitchblende mines of Joachimstahl, and the various lesions produced by external exposure to radium and X-rays, demand investigation, and many of the radioactive substances sold to the public for the cure of various ailments may be dangerous to health. Testifying against the interstate sale of vials of mesothorium and radium which were to be injested after being dissolved in water, Martland reported that he had examined two patients who had taken such water from one to two years and found both to show radioactivity, and both had extensive necrosis of the upper jaw. Martland states that waters which contain only emanation are frauds and he doubts whether they are harmless. The drinking over long periods of time of radioactive waters containing radon, and the drinking of natural radioactive waters, should be discouraged. Martland likewise cautions against the intravenous injection of long lived radioactive elements. (Jour. A. M. A., December 26, 1931, p. 1968.)

CONSERVATION OF HEARING*

J. T. Schlesselman, M.D.
Mankato, Minnesota

THE extent of deafness affords an economic and sociologic problem of a magnitude not generally appreciated. Recent surveys place the number of school children in the United States with defective hearing at three million, and it is roughly estimated that from six to eight million of our entire population are afflicted by a loss of hearing acuity to a greater or less degree. This shows the incidence of six per cent of our people deafened to such a degree as to be hampered in their capacity to enjoy normal contact with their families and society, and also seriously handicapped in acquiring an education and making a living. This puts a heavy responsibility on society, and especially on the medical profession, in trying to remedy this as far as possible. Admittedly, the majority of these cases have only moderate impairment of hearing at first. This, however, may become aggravated and permanent if not cared for early. Otologists hold that by far the greater number of beginning cases of deafness are amenable to treatment, and it is therefore necessary that deafness be detected promptly, so that proper steps can be taken to prevent the condition from becoming chronic.

Due to its insidious onset, deafness, unlike visual and other defects, is not readily recognized, and may be overlooked for a long time by parents, teachers, and the medical profession. In preschool years, and in later life, it is harder to check up than during school years, which time offers the best opportunity for detecting and preventing deafness. Recognizing this, the Section of Otology of the American Medical Association in 1929 adopted the following resolution:

> "Whereas, Recognizing the fact that the most effective means for the prevention of deafness consists in the early detection of hearing impairment, thereby giving opportunity for the prompt removal of contributing causes, and believing it to be one of the important functions of our public school authorities to safeguard the integrity of the special sense organs, as well as the general health of the school child, be it
>
> Resolved, by the American Medical Association, that it heartily favors the provision by our public school authorities for regular periodic examinations of the hearing acuity of all public school children, such examinations to be adequate to detect even slight degrees of hearing loss."

Any satisfactory early detection in the very young is quite difficult and requires the coöperation of parents, general practitioner, the pediatrician, and the otologist. The evidence then is largely circumstantial. The backward and undeveloped child with nutritional disturbances, frequent colds, nasal discharge, adenoids, parasinus and throat affections, and cervical adenopathy, all tending to inflammatory ear involvement, invariably develops more or less loss of hearing acuity.

It will be seen that the care of the deafened child is not necessarily an ear problem, but rather one for the pediatrician. Sanitary, dietetic, and nutritional management underlies all preventive measures.

Various tests have been devised which record with more or less accuracy the kind and degree of loss: (1) conversational voice; (2) whispered voice; (3) watch; (4) forks (Weber, Schwabach, Rinne).

These tests, however, may be classed largely as qualitative tests, they are laborious, and only one person at a time can be checked up. As long as it is so difficult to detect hearing defects in preschool age, it is important that we make use of the opportunity offered in health examinations in schools when we have access to all of our future citizens, and at a time when preventive measures are still available and effective.

The audiometer, an instrument which enables one to test the hearing of groups of children, up to forty in number, is now available. This instrument was devised with the coöperation of the officers of the American Federation of Leagues for the Hard of Hearing, by the technical staff of the Bell Telephone Laboratories. This instrument makes a fairly stable and accurate record of the degree of deafness, and is the only method so far devised which is least influenced by outside interference and errors arising from the human factor of patient and examiner.

---

*Presidential address read before the Southern Minnesota Medical Association, Faribault, Minnesota, August 24, 1931.

In classifying deafness, we must consider three main groups: (1) congenital deafness; (2) acquired conductive deafness; (3) acquired perceptive deafness.

The congenitally deaf do not come into the realm of this discussion; however, a recent report in the Journal of the American Medical Association by Shambaugh on the examination of 5,348 cases in schools for the deaf, gives the interesting data that 62 per cent are congenitally deaf, and of the acquired cases, 50 per cent developed before the age of three. Meningitis causes 20 per cent, measles 8.5 per cent, scarlet fever 7 per cent, influenza 7 per cent. The Wassermann test was positive in only two of 396 cases examined. There was a history of consanguinity in one-third of the cases; three-fifths of the cases had speech defects.

Acquired conductive deafness is the form usually found in early life, and offers the best prospects for amelioration and cure. It is the result of infections and catarrhal inflammations of the middle ear and mastoid, interfering with proper sound conduction to the labyrinth and auditory center.

External diseases and conditions like furunculosis, cerumen, and foreign bodies may cause temporary deafness by obstruction and myringitis. Acute and chronic catarrhal and purulent otitis are most frequent causes, especially when there is mastoid involvement. All these may result from naso-pharyngeal infections of various bacterial origin, through a chronic inflammatory process gaining entry by way of the eustachian tube. Chronic exudative or adhesive catarrhal middle ear involvements are more disastrous to hearing than the acute purulent and inflammatory kinds, because of the insidious and painless onset. Destructive changes of the conducting apparatus frequently go on unnoticed and unattended until serious permanent damage is done to the hearing. The acute fulminating and painful inflammations and suppurations go on to resolution more quickly, because they usually receive proper attention early.

Acquired nerve or perceptive deafness is more prevalent later in life, and is due to constitutional and toxic blood diseases, which do not affect children so often. Some inner ear or perceptive involvements are due to extension from middle ear suppuration, but usually they are idiopathic, the direct results of such conditions as meningitis, typhoid and scarlet fever, measles, diphtheria, influenza, mumps, nephritis, diabetes, syphilis, and focal infections in teeth and tonsils, whose toxins may be destructive to the auditory tract from labyrinth to center in brain. Head injuries are frequent causes of nerve deafness.

Then we have otosclerosis—the mysterious hearing involvement with progressive and permanent deafness, which is due to trophic disturbances and bone changes, possibly an endocrin disturbance.

The prevention of hearing loss requires the care of inflammatory processes of ears in children, adolescents, and adults at the earliest possible time of onset, and the correction of the causes of deafness, when possible.

Proper sanitary living conditions, as to fresh air with proper humidity in dwellings and sleeping quarters, proper clothing, so as to prevent repeated colds and upper respiratory infections, are the first essentials of prophylaxis. Dietetic regulations are of equal importance. Malnutrition, due to lack of fat vitamins, predisposes and underlies deafness. Deafness frequently dates back to an attack of scarlet fever and measles, when the attending physician is satisfied to get the patient over the contagion, while the overlooked ear sequelæ may lead to a handicap every bit as momentous as a heart or kidney complication.

Conditions which may cause deafness, such as head colds, sore throats, nose and sinus infections, and nasal obstructions, should be treated. Forceful blowing of nose, explosions and loud noises, such as those encountered in aeroplanes or in boiler works, diving in contaminated waters (swimming hole earaches) excessive quinine and salicylate medication and direct trauma should be avoided. In acute purulent middle ear involvements, a prompt and proper paracentesis of the drum may save the hearing. The usual conservation of hearing following an early mastoidectomy is most gratifying.

The field of otology has long seemed to offer little which was gratifying to patient and physician, outside of a few measures like mastoidectomy, paracentesis, and removing cerumen; while efforts to help the deaf usually proved futile and useless. Not so long ago the idea prevailed that little or nothing could be done to prevent a child with defective hearing from becoming a deaf adult. It must be remembered that in treating chronic deafness in adults we are tackling the problem from the wrong end.

We know now that we must detect and eliminate the underlying causes early in life. Regular periodic examinations in our schools where we can reach all of our future citizens will, if properly followed up, reduce the incidence of the serious economic handicap resulting from reduction in hearing to a fraction of its present alarming proportions.

HEALTH CONDITIONS IN THE UNITED STATES

In a report recently made to Congress, Surgeon General H. S. Cumming states that reports of the prevalence of communicable diseases received by the Public Health Service from State health officers and preliminary reports of deaths from several sources indicate that the health record for the United States for the calendar year 1930 was exceptionally good. The record for the first half of the year 1931 was also generally good, although an epidemic of mild influenza during the early months of 1931 increased the death rates for a time and gave the year an inauspicious beginning.

The geographic distribution of smallpox in the United States is very irregular. Seven states—Kansas, Delaware, District of Columbia, Maine, Maryland, New Hampshire and Rhode Island—reported no cases of smallpox in 1930. The greatest prevalence of smallpox in that year was in South Dakota, with 259 cases per 100,000 population. Indiana reported 164 cases of smallpox per 100,000 population, and the State of Washington 152 cases per 100,000 population.

During the calendar year 1930 the incidence of influenza in the United States was unusually low. The death rate from influenza for the year 1930 was 18.7 per 100,000 population as compared with 54.6 per 100,000 population in 1929 and 42.1 in 1928. The fact that there was no general outbreak of influenza during 1930 probably helped greatly in keeping the general death rate for the year low, as there is usually an increase in the number of deaths attributed to certain other diseases when influenza is prevalent.

Infantile paralysis was more prevalent during the calendar year 1930 than it was in 1928 or 1929. In the spring of 1930 the reports showed increased incidence of infantile paralysis on the Pacific Coast, and later considerable numbers of cases of the disease were reported in other parts of the country, especially in Louisiana, Oklahoma, and some of the North Central States. In the country as a whole, infantile paralysis reached its peak for the year about the first of October. An outbreak began in New York City soon after the close of the fiscal year. This outbreak later reached considerable proportions, the number of cases being considerably in excess of those reported for the preceding year.

The tuberculosis death rate for the calendar year 1930 was the lowest ever recorded by the Public Health Service. It was 68.5 deaths per 100,000 population as compared with 73.1 in 1929 and 76.4 in 1928. In 1900 the Bureau of the Census recorded a death rate from tuberculosis of 201.9 per 100,000 population. The difference between the tuberculosis death rates of 1900 and 1930 represents a saving of more than 160,000 lives in 1930 which would have been lost from tuberculosis in the United States if the 1900 rate had prevailed that year.

The prevalence of typhoid fever has been decreasing in the United States since comparable yearly statistics of cases and deaths have been available. During the calendar year 1930 a slight reaction was shown by the reports. The increase was reported during the last six months of 1930 and in some States at least it may have been influenced by the drought conditions which resulted in pollution of water supplies or necessitated the taking of drinking water from new or unknown sources. The typhoid fever rates as computed from reports to the Public Health Service were as follows: 1930, 22 cases per 100,000 population; 1929, 19 cases; and in 1928, 22.7 cases.

The case and death rates for diphtheria in 1930 were the lowest which the Public Health Service has ever recorded—54.2 cases and 4.9 deaths per 100,000 population. Ten years ago, 1930, the diphtheria case rate was 155 per 100,000 and the death rate was 15.3 per 100,000.

From 1924 to 1928, there was an increase in the prevalence of pellagra in the United States. In 1929 the reported incidence of the disease decreased somewhat, and there was a further decrease during the year 1930. During the first six months of 1931, however, 16,385 cases of pellagra were reported to the Public Health Service as compared with 13,359 cases reported during the first six months of the preceding year.

More than 1,450 cases of undulant fever were reported to the Public Health Service for the calendar year 1930. The disease has been recognized in every State of the Union.

Rocky Mountain spotted fever is not reportable in many of the States east of the Rocky Mountains. In 1930, 167 cases were reported from California, Colorado, Idaho, Montana, Nevada, Oregon, Washington and Wyoming. During the year workers of the Public Health Service identified, by laboratory and clinical studies, Rocky Mountain spotted fever, eastern type, in several States along the Atlantic seaboard. There is evidence to indicate its existence in this area, at least since 1909. In 1931 cases were reported in the District of Columbia and Maryland.—U. S. P. H. S., Dec. 28, 1931.

THE INJECTION TREATMENT OF HEMORRHOIDS: SOME FALLACIES AND COMPLICATIONS*

W. A. Fansler, M.D., F.A.C.S.
Assistant Professor of Surgery, University of Minnesota
Minneapolis

FROM being the orphan among medical specialties, the past ten years has seen proctology emerge as the Cinderella of the golden slippers. Never before in the history of specialization has there been such a sudden rise to popularity. I believe this unusual interest to be due very largely to the aggressiveness of certain individuals who are giving short courses in proctology on a commercial basis. The average physician has had little instruction in proctology and is anxious to increase his knowledge of the subject. This being the case, he is a ready victim for some plausible individual, who, for a fee of $200 to $500, promises to give a complete course in the diagnosis and treatment of rectal diseases, all in the period of a week or two. The inference is made that the subject is so easy that this short course is all that is needed and treatment is so simple that no further observations are essential to learn all that is necessary to know.

When seriously considered, these inferences and claims, of course, are ridiculous. Complications may arise from any form of therapy and a fellowship in proctology at the Mayo Clinic or the University of Pennsylvania requires three years of study.

The subject usually most stressed in these courses is the injection treatment of hemorrhoids. This is probably because hemorrhoids are the most common of rectal affections and because the hypodermic injection of a solution into the pile seems a most simple matter. Because the procedure is so easy and seemingly harmless there is resulting a crop of unnecessary complications and incomplete cures. These patients are then coming to the surgeon asking surgical relief, being convinced that the injection method is a failure. This is to be regretted for the injection method is of great value provided the operator knows how to use it and knows its limitations and the complications which may arise. It is the purpose of this paper to point out a few practical facts concerning the injection method of treatment and to call attention to certain complications which one is almost certain to encounter if he has a large enough series of cases.

The theory of the injection treatment of hemorrhoids is the injection of a solution either directly into the substance of the pile, *i.e.*, an interstitial injection or the injection of a solution just underneath the mucosa above and covering the hemorrhoid. In either case the result is usually a thrombosis of a portion of the hemorrhoidal vessels and an inflammatory reaction which when replaced by scarification obliterates the varicosities. If it is kept in mind that this is the change which is brought about, many complications can be avoided.

Type of Pile to Inject.—The only type of pile suitable for injection is the internal hemorrhoid, which, when injected, will remain above the internal sphincter muscle. *No other type should ever be injected.*

Solution.—In the past escharotic solutions were commonly used for injection with the idea of producing a slough. At present milder solutions are used with the idea of producing an inflammatory reaction but avoiding slough. A slough is considered an undesirable complication. Enough irritation to produce fibrosis is all that is needed to produce a cure. Quinine urea hydrochloride (5 per cent) or phenol (20 per cent) in equal parts of glycerine and water are satisfactory. For submucous injection 5 per cent phenol in Wessons or olive oil is best. There are exponents of both methods of injection. We use both, the interstitial type of injection for the very vascular hemorrhoids and the submucous injection for those less vascular, and especially where the hemorrhoids are associated with some prolapse of the rectal mucosa.

The average amount is from 1 to 2 c.c. of quinine urea hydrochloride, 5 to 10 min. of the 20 per cent phenol solution and 2 to 5 c.c. of the 5 per cent phenolized oil solution. Of course, more may be used in some cases, but it is better to err on the side of too little. Too large an amount of solution is one of the most common causes of complications.

---

*Read before the Southern Minnesota Medical Association, Faribault, Minnesota, August 24, 1931.

Injection.—If the patient is to be active two areas are sufficient for one injection. If the patient has a sedentary occupation or is not working, the complete ring may be injected at one sitting. It is safer to inject a smaller number.

Too frequent injection is also a very common cause of complications. Most texts and papers state that the hemorrhoids should be injected every three to seven days. This is a serious mistake. The period between injections should not be governed by time. The only criterion is the condition of the hemorrhoid. If there is induration still existing from the previous injection it should not be reinjected. Whether it be a day or a month one should wait until the induration has subsided.

The minimum time under favorable circumstances in which a cure may be promised is four weeks. We prefer to take eight weeks. If speed is necessary surgery is more certain, and I believe safer.

There is no way of telling in advance exactly how many treatments may be necessary to produce a cure in a given case of hemorrhoids. We can only be sure that a case is actually cured, when, upon examination, after all induration has subsided, no hemorrhoids are present.

Complications.—Usually these are not of serious character although fatalities may occur.

Most patients complain of some pain. Any pain, however, which is more than a dull ache and lasts more than a few hours should be classed as a complication. Severe pain usually results from injecting the solution too low down, that is, into an anal or external hemorrhoid. In some cases this pain may be severe and continuous for from three to ten days. Pain also may follow a slough, especially if the slough is near the ano-rectal junction. Pain is also present where an abscess forms, complicating the injection.

Slough is probably the most common complication. Personally, I would not believe anyone who does any considerable number of injections and says he never had a slough. Usually the slough is superficial and no ill-effects are noted. In fact, unless an examination is made, neither the patient nor the physician is aware that it has occurred. It is usually caused by the solution being injected too superficially or in too large an amount, or the injection being made into a hemorrhoid which is still indurated from a previous injection. While sloughs are usually of no permanent consequence they may be severe. Buie reports two cases where the tissues of both ischio rectal fossæ almost entirely sloughed away. Other complications which may follow a slough are hemorrhage, adenitis, fistula and septicemia.

Hemorrhage usually follows a slough. This is in most cases slight in quantity but an artery may be opened up which may produce alarming symptoms. A drop in hemoglobin to 40 or 50 per cent may occur. It is not always possible to tell when the bleeding begins as the blood backs up in the colon. The first intimation that a hemorrhage has occurred is a desire to evacuate the bowel. Then the patient may pass a pint or even a quart of blood. If one is unfortunate enough to have this complication occur, a speculum should be inserted, the bleeding vessel sought out and a stitch put around it. Anything less than this is a waste of time.

Occasionally an abscess instead of a slough may form. This may appear as a swelling near the margin of the anus and must be opened externally. In this case there is a complete fistula to deal with. At times nothing appears externally and a submucous abscess develops which breaks or is opened into the rectum. I have seen three cases where the slough or abscess as the case may have been, opened into the vagina producing a recto-vaginal fistula. I have been fortunate enough not to have this complication occur in any case I have injected myself, but where the recto-vaginal septum is thin from the lacerations of child bearing it is well to be very careful in injections on the anterior rectal wall.

With an abscess or slough adenitis may occur. I have seen the inguinal glands involved and I am sure that in some cases the deeper pelvic glands may also become involved. A temperature of 101 to 103 is not uncommon in these cases. In all cases I have seen, the inflammation has subsided without suppuration.

Liver abscess is a rare complication. Authentically, I know of but one case reported in the literature. In times passed this complication was brought forth as a "bogeyman" by all opponents of the injection method. It occurs but seldom but it cannot be ignored.

A few very severe systemic reactions have been reported following the use of quinine urea hydrochloride. This is due either to an individual or familial idiosyncrasy to quinine. Rapid thready pulse, prostration or syncope, with or without skin eruption, are the common symptoms. Severe reactions to phenol are more rare.

Strictures are of two types. The first follows extensive sloughs and is caused by cicatrization of the healing process. Needless to say, this is an avoidable complication. Rosser recently reported a stricture due to the use of a large amount of oil solution where globules of oil became encapulated in areas of scar tissue.

Failure to secure a cure should probably not be classed as a complication. Yet it occurs so frequently it should be emphasized. It is due to but three things: the improper selection of cases, an improper method of the injection, or discontinuing the treatment too soon. The last named is probably the most important.

In conclusion I want to say that this paper is not presented with the idea of discouraging any one from using the injection treatment of hemorrhoids. Rather it is a plea for a more thorough investigation and general understanding of the method that it may not be discredited by indiscriminate and improper usages. The operator should realize at the onset that the method is not as simple as it sounds and that a thorough understanding of all the processes occurring during the entire course of treatment is necessary if complications are to be avoided and good results secured. Lastly he should know the complications which occasionally arise even under the most careful treatment and know the best methods of dealing with them. With this knowledge the injection method will be found to be most satisfactory both to the patient and the physician.

THE INTRAVENOUS USE OF BARBITAL COMPOUNDS

The Council on Pharmacy and Chemistry reports that more than seven years have elapsed since the introduction of the intravenous use of barbitals, sufficient time to justify an assay of the possible value of the method. Since the chief object of the intravenous use has seemed to be the possible employment of barbitals used in this way to produce anesthesia, the Council reports on the possible changes following intravenous injection, a comparison of the experimental and clinical results, and attempts to determine if the intravenous use has peculiar advantages over other methods of administration, with equal safety. The Council points out that there is no doubt that the characteristic hypnotic action of the barbitals can be obtained by oral administration; that since the barbitals act essentially as hypnotics, and not as anesthetics, it is reasonable to entertain doubts about radical departures from the orthodox usage of these drugs, but the new methods of using and new uses for well known drugs merit attention; and that, moreover, the intravenous use of barbitals has been widely exploited by some manufacturers and serious attention has been given to the subject experimentally and clinically. From an exhaustive review of the literature it is concluded that any advantages that may exist in the choice of barbitals as aids in anesthesia, or as sedatives, analgesics or hypnotics, can be easily procured by giving them by mouth, with the further advantage of avoiding the necessity of the small operation and aseptic technic for intravenous injection and the unnecessary disturbances and complications of such injections in general, and that about the only argument in favor of the intravenous route would be an occasional rapid action in an emergency, and that hence their intravenous use should be limited for the present to conditions in which oral administration is not possible or when a very prompt action is imperative. (Jour. A. M. A., December 19, 1931, p. 1886.)

SEVENTEENTH CENTURY PEDIATRICS*

AN ANTHOLOGY

O. W. Rowe, M.D.
Duluth

A DISCUSSION of the men who contributed to pediatric progress in the 17th century must give some consideration to the work done by their predecessors, both remote and immediate, as well as to the habits of thought of their contemporaries in other branches of science. Events political, economic and religious, difficult to interpret without reference to world conditions have a distinct bearing on the type and quality of scientific productions. There have been periods in history when statesmanship made great strides, while medicine failed to register any noticeable progress. An example is found in the closing years of the preceding century. Queen Elizabeth of England established herself as one of the greatest ministers of statecraft, furthering peace and cementing a firm government, but she gave little consideration to public health or encouragement to medical research. Her father, Henry VIII, is credited with the initiation of vital statistics. The beginning was simple. He ordered that the incumbent of parishes keep a true and exact record of marriages, christenings and deaths. Possibly he feared his own marital adventures might so influence his subjects that some form of national bookkeeping would be useful. Elizabeth enlarged slightly upon this idea, but no real progress was made until the appearance of the Black Death. While she dallied with her lovers she allowed to slip away her day of grace so far as motherhood was concerned, and so ended the reign of the Tudors. Had she encouraged medical progress, particularly therapeutics, she might not have had to take for her dropsy that terrible concoction of strange ingredients prescribed by Gilbert. Elizabeth, shortly before her death, made amends to Mary Stuart by nominating James for the Crown. This monarch brought many of his favorites with him from Scotland but retained a few counselors from Elizabeth's reign, including Cecil, Bacon and Gilbert. The latter continued to hold the position of Royal Physician. Gilbert was more interested in physics than in medicine. It was in the first year of the 17th century that he brought out his epoch-making work on magnetism, the starting point of all subsequent work on terrestrial magnetic variations. Dryden's encomium, "Gilbert shall live until lodestones cease to draw," is still true. Such men exert a profound influence on the scientific thought of their contemporaries.

Among the many geniuses following Elizabeth's reign, none exerted a more profound influence on clear, concise thinking than Bacon. We should feel grateful for his influence upon Sydenham and Mayow. Kept in the background by his kinsman Cecil, he had little opportunity of demonstrating his power until the latter's death. His influence while he enjoyed royal favor and even after he was overthrown and living in forced retirement was a great stimulus and example to his contemporaries.

Civil disturbances in the latter part of James' reign and later under Charles I, culminating in the rise of Cromwell, did not interfere with scientific progress.

Moral and religious conditions, varying from the intolerance of Cromwell to the license of Charles, whose court was characterized as the "most scandalous in Christendom," encouraged a type of mental gymnastics which must have amused such men as Defoe, Dryden and others of the period.

It is conceivable that the disquieting time under James II was not improved after he ran away to Paris. William of Orange on his arrival from the Netherlands imposed many religious conditions which might easily have deflected the progress of scientific thought. While some possibly were intrigued or discouraged by politico-religious events, others found the times stimulating. This was not only true of physicians but of other outstanding characters. Certainly men like Butler, Bunyan and Milton found this period not altogether to their liking but the civic unrest did not retard their work. It was at this time that Wren rebuilt that portion of London which had been destroyed by fire shortly after the Black Death.

---

*Presented at the Pediatric Seminar, University of Minnesota, June 10, 1931.

In Central Europe, at the beginning of the 17th century, conditions were ripening for the Great War. Religious agitation, continuous for more than seventy years, finally culminated in the storming of the Council Hall at Prague. This incident started the Thirty Years War in much the same manner as a comparatively trivial event precipitated the World War. During the war and the years of reconstruction that followed, the German people found conditions little suited for the advancement of science, particularly medicine.

The politico-revolutionary movement begun in England spread in much the same fashion as the Reformation. In general, the effect was as varied as the races of the countries in which it struggled for recognition. The result was to stifle the progress of science except in the more phlegmatic countries like England, Holland and bilized.

Isolated exceptions were encountered in other countries even in the first years of the century. In France, where the institution of royalty had been consolidated to a point which made the monarchial structure seemingly imperishable, little consideration was given to child welfare. Cruelty to children was a national crime. This naturally led to a reaction which resulted in certain laws regarding the abandonment of children and the development of such movements for their welfare as that instituted by St. Vincent de Paul. The early years reveal the name of a French physician, Ballou or Ballonious. While he was active at that time his works were not published until after his death. He was much interested in the influence of climate and season on the prevalence of epidemic diseases. His article on whooping cough is quoted in Rurah's Pediatrics of the Past. This remarkable character wrote, as did Sydenham, in much the same vein as Hippocrates. He was called by Crookshank the first epidemiologist of modern times.

Conditions in America were not propitious for the development of medicine. Jamestown, the Plymouth colony and the New Netherlands naturally drew to them a number of European physicians, who, as in Russia, were active agents in advancing the interests of ligitimate medicine. Prominent among these were Bohun, Pot, Samuel Fuller, who came over on the Mayflower, John Winthrop, Jr., and Thomas Thatcher. The latter was the author of the only medical publication printed in the North American colonies in the 17th century. This contribution was the "Brief Rule to Guide the Common People of New England How to Order Themselves and Theirs in the Small Pox or Measles." Thatcher, in addition to his medical work, found time to become an excellent scholar in Hebrew and Arabic. He was also the first pastor of the old South Church in Boston.

The greatest name in 17th century medicine is that of William Harvey (1578-1657) of Folkstone in Kent. He was educated at the King's School, Canterbury, and was nominated to a scholarship preparing one for medicine at Cambridge.

Padua had been the greatest school of medicine for some time and Harvey went to that place which Vesalius and others had made famous. The University was governed largely by the students of the different nationalities. Harvey was chosen councilarius, an office which John Finch said entailed being "drunk at least forty times in the year." The teacher who had the greatest influence upon Harvey was Fabrica. This teacher, who performed his dissections in the amphitheater by candlelight, was greatly interested in the mysteries of the circulation. He demonstrated the valves in the veins and made many notable contributions to the subject of development. While Harvey made no direct contribution to pediatrics his work on "De Motu Cordis" produced a definite and far reaching effect. The crux of Harvey's argument as described by Garrison—"that the actual quantity and velocity of the blood, as computed by him, make it physically impossible for it to do otherwise than to return to the heart by the venous route"—was the first application of the idea of measurement in any biologic investigation. "Had he chosen to express his discovery in the language of algebra it would have taken its proper place in the application of mathematical physics to medicine. The importance of Harvey's work is not so much the discovery of the circulation of the blood as the qualitative or mechanical demonstration." With this start physiology became a dynamic science.

From the pediatric point of view the most interesting contributions of the 17th century were made by Walter Harris (1647-1732). His book on "Acute Diseases of Infancy" was referred to by Sydenham as one which "may be of more service to the public than all my own writings." In that treatise he broke away from the popular Hippocratic pathology of humors and affected the acid diathesis of Sylvius, viz: that "all the symptoms of gastro-intestinal disorders owe their origin to acid products in the body." He extended the concept of infancy beyond the classical three months of Galen to the fourth year, and extended the period of childhood to fourteen years.

The difficulties and discouragements of pediatric practice made a deep impression upon Harris. He believed "that the cure of a sick child was as much to be desired as anything in the whole Art of Physic, and of consequence not only to the nobles, wealthy and powerful, but to parents of any rank whatsover." He discoursed at length on the value of history and observations obtained from nurses, upon the hereditary influence in children's diseases, the importance of correct diet, and the advisability of limiting opiates and wine. Concerning the latter, however, he held different views regarding its use in later life. He insisted upon specific directions, noted the seasonal appearance of diarrhea and painted gruesome pictures of marasmus and convulsions. His book held its place for 100 years, or until Underwood's work supplanted it. While Harris was not as great a physician as some others of his time, he was a shrewd, honest practitioner of pediatrics, a keen observer who taught simplicity, caution and common sense.

A far greater name is that of Thomas Sydenham (1624-1689). He was not a pediatrist, but a general practitioner, a man without hospital connections or official office of any kind, not even a Fellow of the Royal College, yet he left his imprint upon medicine for all time. He revived the Hippocratic method of observation and experience. In fact, he stands as a representative of the clinical and bedside approach to the problems of disease, just as his contemporary, Harvey, stands as a prototype of the experimental investigator.

Sydenham had little patience with the laboratory or with research, largely, Reisman believes, because of the preposterous claims and fanciful theories resting upon meager data. The scientific theories of the time were of little value to him at the bedside. He relied upon his powers of observation and his fund of experience.

Sydenham had a late start in his medical career. He was born of Puritan parentage in Dorsetshire, a place called by Lord Clarendon "the most malignant spot in England." It is not strange that this Roundhead felt impelled to leave Oxford to take service in the Army. Later he returned to Oxford, but took his degree at Cambridge at the age of fifty-two.

There had been sporadic instances of accurate descriptions of disease before the time of Sydenham. Glisson had given his classical description of the English disease, and Mayow, the greatest genius of the century, had shown evidence of his powers of observation and deduction, but Sydenham was the first real clinician of modern times to observe and record the progress and treatment of disease. He drew sharp distinction between acute and chronic disease. He laid much stress on bodily disposition, age, sex, season and climate, and their influence on the course of disease. His description of gout and stone (he suffered from both), and of smallpox are unsurpassed. He is credited with being the first to describe and name scarlet fever. He did not, however, recognize the sore throat or the fact that it was contagious. He introduced the so-called cooling treatment, used the bark discovered by the Jesuits in the treatment of ague and invented the mixture not unlike our wine of opium, called Sydenham's laudanum. He believed that a patient making satisfactory progress should be let alone and not drugged. He pointed out that the secondary manifestations of epidemics varied from time to time and that one complication was more prominent at one time than another.

In Sydenham's last work on the appearance of a new fever, appears his masterly description of chorea. While not as accurate as his work on gout, it is the study by which he is best known.

What Sydenham's attitude toward experimentation might be today we can only surmise, but he surely was not reactionary in temperament and would have undoubtedly welcomed every aid to his understanding of disease.

I have just named John Mayow (1643-1679) as the greatest genius of his time. But he was a neglected genius. During his life he did not attain the position he should have held and even now he is comparatively unknown. His recognition of oxygen and of combustion led to his remarkable work on respiration. This work was influenced by Lower, the brilliant experimental physiologist, on whose skillful dissections much of the reputation of the more famous Willis rests. He showed that the maternal blood supplied the fetus with oxygen as well as food. His work in chemistry was brilliant. His death at the age of thirty-six is said to have delayed the advance of modern chemistry more than a century.

From a pediatric standpoint his description of rickets is of interest, especially that portion which deals with diagnosis. His observations, presented in terse, short sentences, are remarkable when compared to the verbose reiterating style of Glisson.

Francis Glisson (1597-1677) was one of the brighter lights of English medicine in the 17th century. His work on the anatomy of the liver will always be remembered as his name is associated with the capsule. He was the first to use the word and the idea of "irritability," which means so much to modern physiology. His work on rickets is the foundation of our knowledge of this disease. Some consideration may well be given to the limited knowledge of rickets existing in Glisson's time.

Whether rickets was to be considered a modern disease or whether it was equally prevalent centuries before was a subject for much discussion. Statements by Greek and Roman philosophers and physicians which seemed to refer to this disorder are not sufficiently precise to convince one that they did not refer to some other disease accompanied by deformity of the bones.

The most remarkable feature in relation to the history of rickets was the sudden appearance, or at least marked increase in incidence in the 17th century. To such an extent was this manifested in England that a commission was appointed with Glisson at its head to gather reports and communications relative to the disease.

Glisson's publication was preceded by five years by a little book written by Daniel Whistler after that worthy had been elected "in an evil hour" to the presidency of the College of Physicians. The fact that this man had heard of rickets rather than studied it is fairly evident from his book. At least one other mention of rickets had been made previously, namely, an article by one Arnold De Boot, a Dutchman serving in the English army.

Glisson had as his collaborators six men, all members of the College of Physicians. They collected papers and communications made at private meetings and attempted to edit the material. When Glisson had interwoven his part containing many views differing from those commonly held, they committed the whole work to him in order to avoid deformed and misshapen statements. His work comments on the antiquity of the disease, dwells on the fact that it is not luetic in nature, devotes chapters to anatomical observations before the body is opened and after, gives a long account of the changes in the bones, with resulting deformities, speculates on the causes, including diet and "such things as are taken inwardly," puzzles over the fact that it is not observed until the sixth month, refers to its association with other diseases, especially scurvy, and gives a good account of the signs and symptoms. His therapy was that of the period.

This lengthy report reminds Ruhrah of the remark that Milton's Paradise Lost is a fine work but no one has been known to wish it one line longer.

The work is a monument to Glisson's powers of observation and description and is so complete that, apart from the information afforded by technic not at his disposal, little has been added since.

The name of Robert Pemell (?-1653) is not among the great in English medicine, yet he made a valuable contribution to pediatric literature by his book on "Diseases of Children" and later by a popular treatise entitled "Help for the Poor." In this he established himself as being in the vanguard of welfare workers. It considers the diseases of children, particularly those common among the indigent. It shows him to have been a pioneer among those interested in the prevention of infant mortality. His therapy employed was the usual absurd remedies of his day, but included baths, the external use of wine and of sulphur for suppurating skin diseases. All of his remedies had the merit that, if they did not help, they did not harm.

His chapter on worms shows that many of the symptoms now attributed by the laity to this infection are not of recent origin but existed during his time. After citing a number of these vagaries he closes his chapter on diagnosis with the statement that "The most certain sign of all is when they void worms in the excrement." He was an author of merit, a technician of ability, a pediatric thinker in some ways ahead of his time and one of the early workers in the field of infant welfare.

If we were to consider Francis Sylvius (1614-1672) solely from his pediatric work we would do rank injustice to this great man. He wrote a little pediatric text in "Familiar style for weaker capacities" which was published in Amsterdam and later in London. In it is combined a treatise on rickets. It contains much common sense, but some absurdities, most of which are a reflection on the time rather than the man. He is best known as an anatomist, his name being connected with at least five portions of the brain. He also was a brilliant teacher, physiologist and clinician. Students from all over Europe flocked to his clinic at Leyden, among them Willis, who concentrated on the study of the brain, aided by the neglected Lower, De Graff of the graffian follicles, Stensen, Swammerdam, who described the red corpuscles, and Van Horn of thoracic duct fame. No student of the time who had not attended his dissections felt that he knew anatomy. His method of clinical instruction has been much quoted and is followed by many of the great teachers of today. Naturally, with the limitations of his time, many of his concepts were incorrect, but he gave a great impetus to medical observation and thought.

To credit all the men who contributed indirectly to the progress of pediatrics in the 17th century would require some discussion of most of the physicians whose names still live, and many outstanding characters in other sciences. The progress made was not limited to the cure of the child but included social and cultural aspects as well. Painters who previously had used children only for religious pictures were awakened to their artistic possibilities. Musicians and sculptors for the first time recognized the child as an asset. Previous to the time of Hugo, the child occupied an infinitesimal place in literature.

From a pediatric standpoint the effect of the 17th century workers can be classified under three heads:

1. The recognition that the life of a child might be worth saving. This was a new concept. Development of the movement we know as infant welfare really began in this century.

2. The influence of Harvey which resulted in an age of specialized anatomic research which was notable for its long array of individual discoveries and investigations, nearly every one of which had a physiological significance. This was responsible for the immediate advancement of medicine, yet it contained much faulty philosophy. Its votaries were primarily philosophers and secondarily physicians.

3. The effect of the school of Sydenham, which actually observed and recorded the progress of disease. It was responsible for the development of clinical medicine.

To us, the influence of colonial medicine on the type of practice existing in America for a long period following this era is interesting. This was due, Garrison believed, to two factors: (1) the youth who studied with a physician under indentures of apprenticeship received actual bedside instructions from the start; and (2) under primitive frontier conditions the medieval antagonism between the physician and surgeon soon disappeared for the necessary and sufficient reason that the frontier doctor was called upon to meet any emergency, surgical, obstetrical and medical. As Handerson says, "Many of these apprentices doubtless proved as successful physicians as some of their more fortunate colleagues who boasted an M.D. of Leyden, Aberdeen or Cambridge and "Slew their patients" "Secundum Artem." We may agree with the same authority that, from this period on, American medicine acquired the eminently practical tendency which has been its chief merit.

CASE REPORTS

FRACTURE OF THE TEMPORAL BONE

REPORTS OF TWO CASES WITH UNUSUAL SEQUELÆ

John F. Curtin, M.D., and
Lawrence R. Boies, M.D.
Minneapolis

Involvement of some portion of the temporal bone in skull fracture is common. The more serious injuries in which the temporal bone chiefly is concerned, usually involve the petrous portion.

The main types of temporal bone fracture can be briefly classified as follows:

I. Longitudinal

(a) Usually run along the anterior border of the pyramid beginning in the anterior fossa or in the region of the Gasserian ganglion, and ending in the tegmen antri or tympani and external auditory canal. The facial nerve may be involved.

(b) Posterior to the pyramid and involving chiefly the mastoid process and bony covering of the lateral sinus.

II. Transverse

Comparatively rare. Cross the pyramid at right angles and usually at the weakest portion, the region of the vestibule. Unless the lateral wall of the inner ear is involved, which is rare, hemorrhage from the ear does not result.

III. Avulsion of the tip.

Very rare. This type should not affect the inner ear but may cause injury to the nerves at the internal auditory meatus.

Labyrinthine fractures show a tendency to close by fibrous instead of bony union, and therefore a late meningeal infection from the middle ear is an ever present possibility.

Objective examination of the auditory and vestibular function reveals the seriousness of the injury as far as damage to the temporal bone alone is a factor.

The following cases of skull fracture involving the temporal bone are of particular interest because of their unusual sequelæ:

Case 1.—A six and one-half year old girl was hospitalized in a semi-conscious condition on September 3, 1930, an hour or two after being struck and knocked to the pavement by an auto. Examination revealed a fractured ankle and multiple body bruises in addition to a bleeding left ear with ruptured membrana tympani. She seemed totally deaf in the injured ear; the escape of cerebrospinal fluid was not noted. A basal skull fracture was suspected although the plates taken of the skull (stereoscopic lateral) were negative. She was seen on the day after her injury by Dr. Curtin at the request of Dr. T. W. Weum.

Her general condition improved during the following week, but she complained of pain in her left ear. No significant neurological symptoms were evident; she had been conscious since a few hours after her admission to the hospital. The fractured ankle had been reduced and immobilized; her bruises healed. A serosanguinous discharge from the ear on the day following injury had developed a mucopurulent character with an increase in amount. Moderate pressure over the cortex of the mastoid elicited considerable tenderness.

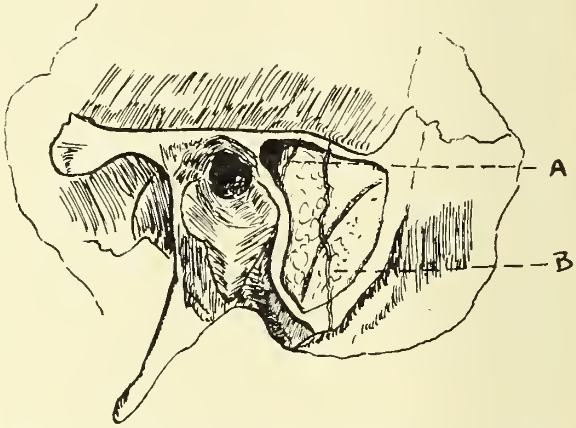

Fig. 1. Diagrammatic representation of site of fracture lines, *A*, Case 1; *B*, Case 2.

On September 12, a partial left facial paralysis was noticeable. No other significant signs were evident except a slight increase in the amount of discharge. The X-ray examination indicated a pneumatized left mastoid, clouded, and without definite evidence of cell destruction. There was a rise in temperature on the next day to 101 degrees (mouth); the facial weakness was more marked and she complained of pain over the left side of her head. There was also some sagging of the postero-superior canal wall. The leukocyte count was 19,000. Her febrile manifestation is indicated on Chart I (only the morning and evening temperatures are recorded, as they show the general trend, though four hour temperatures were kept).

On September 14, left simple mastoidectomy was performed (Dr. Curtin). Considerable destruction was evident especially about the antrum in the region of the zygoma and toward the solid angle. A line of apparent fracture was observed extending through the tegmen of the antrum. All cells were exenterated.

Convalescence was uneventful. The facial weakness completely cleared and she was discharged home on the twelfth day after operation. At the time of discharge, however, the middle ear, which at first had been dry following operation, was again discharging a little, and she complained at times of a dull left sided headache.

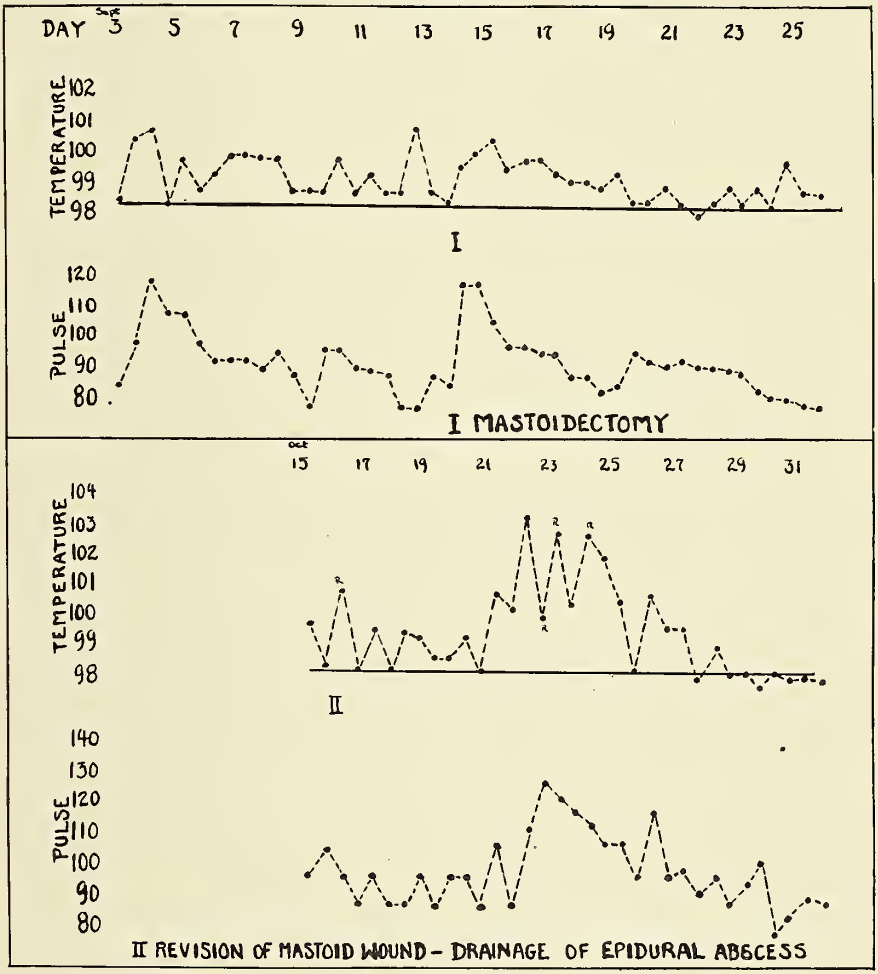
There followed an eighteen day period at home. During the first week slow improvement was noted. In the second week, she was feverish at times and there was an increase in the frequency and severity of headache over the left temporal area. She was readmitted to the hospital on October 15, at which time her temperature was 101 degrees, there was an increase in discharge from the middle ear, and drainage from the post-aural wound, and she complained bitterly of headache. The white blood cell count was 13,000. Dr. H. B. Hannah saw her in consultation; the neurological examination was negative for evidence of intracranial disease or meningitis.

A secondary mastoidectomy was performed on October 16. There was evidence of delayed healing in the wound. No cellular structure was noted. The line of fracture traversing the tegmen of the antrum was again observed. At this site, an area of dura over the middle fossa was uncovered revealing a large epidural abscess, which was drained. The lateral sinus plate was also removed from knee to tip; the sinus appeared to be normal.

The post-operative course was marked by some immediate improvement. Her headache was relieved but did not entirely disappear. Toward the end of the first post-operative week it became more severe. The temperature curve is shown on Chart I. On October 21, there was a sudden rise in temperature to 101 degrees (mouth). On the next day she complained continuously of severe headache; a stiff neck and a positive Kernig reflex had developed. A lumbar puncture revealed a cloudy spinal fluid under 28 mm. of mercury pressure and a cell count of 2,275, ninety-five per cent of which were polymorphonuclears. No organisms were found on smear or culture. For two days her condition remained about the same, the temperature being elevated and headache severe. She vomited several times. Another spinal puncture, on October 24, showed marked improvement of the spinal fluid with a cell count of 611.

Gradual improvement followed; she left the hospital on November 1. Subsequent examination showed an

CHART I



intact left ear drum completely healed, a healed post-aural wound, total deafness in the ear and no evidence of vestibular abnormality. On August 1, 1931, she was in excellent general health.

This case illustrates the longitudinal type of fracture involving the petrous portion of the temporal bone, with fracture line through the tegmen of the antrum. The absence of vestibular phenomena would suggest that the fracture involved the cochlea, inasmuch as complete deafness resulted in the affected ear. If deafness was due to injury of the eighth nerve in the internal auditory canal, one would expect evidence of vestibular disturbance. The absence of escaping cerebrospinal fluid from the ear points toward no injury at the internal auditory meatus, as it is here that the meninges are prolonged into the meatus, and a tear in them with rupture into the subarachnoid space accounts for the escape of cerebrospinal from the ear in these cases.

The development of an otitis after this injury is accounted for by infection of the middle ear through the eustachian tube. The probable effusion into the mastoid of blood and serum following injury formed an excellent medium for suppuration to start.

The later development of the facial paralysis in presence of evidence of a suppurative otitis media rather indicates that this was due directly to the infection and not to anything cerebral. It is certain that there was no involvement of the facial nerve directly from the injury or there would have been some indication of it at that time. The onset eight days after the injury, with the most significant symptoms at that time related to an otitis media, is conclusive evidence that the paralysis was directly the result of the suppurative process. This is supported also by the subsequent course of events.

The manner of development of the pathological process that followed the mastoidectomy must in part be a matter of speculation. The location of this epidural abscess indicates the probability that the break in bone at the site of this abscess was a definite factor in its occurrence, although epidural abscesses are not uncommon complications of middle ear infections without temporal bone fracture.

Dr. Hannah believes that the symptoms following drainage of the epidural abscess, and the spinal fluid findings, indicate that a small intracerebral abscess developed which ruptured and drained into the subarachnoid space. This seems the most logical conclusion.

Case 2.—A six years old boy was admitted to the Pediatric Service of Dr. E. J. Huenekens at the Minneapolis General Hospital on April 28, 1931, an hour after he had been struck by an auto. He was still unconscious. Except for a few superficial bruises, some dried blood in his nose, a little fresh blood in his nasopharynx, and the presence of bilateral Babinski reflexes, his examination on admission was negative. He vomited several times during the next twenty-four hours.

He was still unconscious on the following day. There was evidence of a partial left facial paralysis. A lumbar puncture showed a spinal fluid pressure of 250-340 mm. of water, and blood due to the puncture.

During the following week, he continued to be unaware of his surroundings, but could be partially aroused and was irritable when touched. Consultation by the neurological and surgical services failed to elicit additional signs of any significance.

Gradually he became brighter. The facial weakness cleared. On May 21, he had developed measles and was transferred to the contagious ward. On June 2, a myringotomy was done on the left ear drum. No secretion was obtained.

His temperature rose to 105 degrees on June 6 (Chart II). The ear had begun to discharge pus. The patient rapidly developed a toxic appearance and seemed to be losing strength. An X-ray examination indicated destruction of the left mastoid. It was also noted that there was a line of lessened density just posterior to the tip of the mastoid and running superiorly and inferiorly, which suggested a possible fracture in this region.

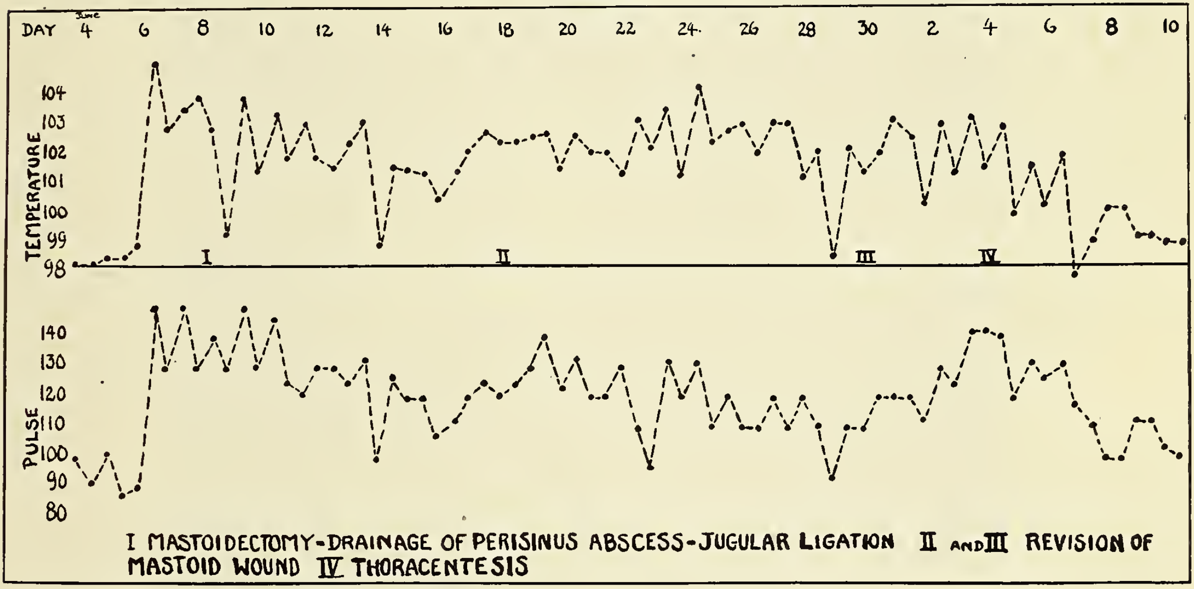
A simple mastoidectomy was performed on June 8 by Dr. Boies. On retracing the periosteum over the cortex, a fracture line was noted, the course corresponding to B, Figure 1. The cortex was removed with gouge and curette, revealing a mastoid in coalescent stage. All cells were exenterated. When the bony plate over the lateral sinus was exposed, a fracture line could be seen crossing diagonally throughout. The sinus was uncovered As the plate toward the tip was removed, pus welled up from a large perisinus abscess. At this point a portion of the lateral sinus wall, apparently necrotic, gave way when sponged and profuse bleeding followed which was controlled by an iodoform plug inserted in the space between the bony wall and the compressed sinus. Because of the presence of a phlebitis, and a probable thrombosis, as well as for the control of hemorrhage, a left internal jugular ligation was performed at this time. The mastoidectomy was then completed and the sinus packed off above the iodoform plugs.

The post-operative course was not particularly encouraging during the following week. On the third post-operative day, the sinus packs were removed but had to be replaced as complete thrombosis from the torcular end had not taken place. In three more days they were removed without further bleeding. A transfusion was also given. The temperature continued to be elevated and the patient's general condition did not improve.

On June 18, the mastoid wound was explored in search of the cause of his apparent general sepsis. Repeated general physical examinations were negative. There was little evidence of healing. A portion of the tegmen of the mastoid was removed at the site of the fracture line. The dura was injected; a small amount of granulation tissue covered it over the area exposed. This bled easily. No pus was seen. Further exposure of the lateral sinus was made by uncovering toward the torcular end. The central portion of the sinus had become obliterated and the portion toward the torcular end appeared healthy. There was nothing significant toward the bulbar end.

The post-operative course again was not encouraging. He continued to be rather drowsy, irritable when touched and the temperature remained elevated (Chart II). A bilateral positive Kernig reflex and some neck rigidity were elicited. Lumbar puncture revealed a normal spinal fluid pressure, a cell count of 22, eighty-five per cent of which were polymorphonuclears, and no organisms. Dr. J. C. Michael of the Neurological Service thought that he had an early meningitis. A myringotomy was performed on the right ear because of a thickened membrane tympani; no secretion was obtained.

CHART II



On June 30, the mastoid wound was again explored. The patient had continued to be critically ill and repeated general physical examinations by Dr. Huenekens and others had revealed nothing to account for his continued symptoms except the aural disease. At this operation (Dr. Curtin and Dr. Boies) a larger area of dura in the middle fossa was exposed by removal of the tegmen of the antrum and of the mastoid. The bone seemed to be very soft and devitalized. The whole mastoid cavity indicated that there had been little evidence of healing. Additional soft bone was removed in front of and behind the lateral sinus. The thrombosed sinus was incised and a portion of the clot removed from both ends; it appeared to be healthy.

On the day following this operation, chest symptoms developed, with elevation of pulse and respirations. His temperature continued elevated as shown in Chart II. Signs of fluid developed and on July 4, 100 c.c. of clear yellow fluid was withdrawn from the right pleural cavity.

A period of gradual improvement followed. He was given three transfusions during the following month and was able to leave the hospital on August 5. An abscess at the site of an hypodermic puncture in his left deltoid muscle had delayed his discharge from the hospital.

There was no evidence in this particular case, from an otologic standpoint, that the petrous portion of the temporal bone had been involved. The injury through the mastoid process probably resulted in the presence of serum and blood within the mastoid as a direct result of the injury. However, the development of an otitis in this case may not have been influenced by the local injury, inasmuch as the injury was followed by an attack of measles.

The fracture through the lateral sinus plate was undoubtedly a factor in the development of this perisinus abscess. There was evidence also that the infection reached the meninges above the fracture line through the tegmen of the mastoid. This probably was a prominent factor in the symptoms subsequent to the initial operation.

The appearance of chest signs occurred after the final operation on the mastoid. Repeated general physical investigation over a three week period between the initial and final mastoid operation had failed to reveal anything to account for the symptoms of that period. It is reasonable to assume, therefore, that they were the result of infection within the mastoid and its environs. Experience with similar cases in which areas of devitalized bone had to be removed before healing resulted, leads us to the belief that the final removal of all involved bone with wide exposure of the adjacent meninges was a definite factor in the recovery.

COMMENT

In cases of head injury with suspected fracture of the temporal bone, objective examination of the auditory and vestibular function indicates the seriousness of the injury as far as the temporal bone is concerned.

The development of a middle ear infection following fracture involving the petrous portion of the temporal bone, with extension of the fracture into the middle ear, or tegmen of the antrum, or following fracture of the mastoid portion alone involving the pneumatized portion or sinus plate, demands especially careful observation for signs of more serious complication which might arise due to the break in the bone. It is generally agreed that early intervention is indicated under these circumstances when signs of mastoid infection develop.

Persistent attention to the mastoid wound is necessary when symptoms of sepsis or delayed healing are evident and contributing causes elsewhere have been ruled out.

TUBERCULOUS PERICARDITIS

REPORT OF A CASE WITH RECOVERY

E. H. Jorris, M.D.
Excelsior, Wisconsin

Tuberculous pericarditis, while more common than is generally thought, probably occurs less often accompanying a childhood infection than an adult infection. Autopsy statistics show that in 25 per cent of all cases coming to post-mortem examination there is some tuberculous lesion present; in 1 per cent, tuberculosis of the pericardium has been found. Norris reports 82 cases of pericardial involvement in 1,780 autopsies on known tuberculous patients. Others report similar figures, averaging from 4 to 7 per cent. German figures show pericardial involvement in tuberculous children to be about 3 per cent.

Although tuberculous pericarditis is occasionally a primary lesion, it is usually a secondary infection and a coexistent pulmonary, bone, visceral or mediastinal lymph node involvement can be found. It must be remembered that there is a free communication between the pericardial cavity and the peritoneal and pleural cavities by way of the lymph channels.

The symptoms of tuberculous pericarditis are obscure and the diagnosis depends upon the finding of the primary lesion or definite evidence of a tuberculous infection. The patient has fever, a few chills. usually dyspnea and pain, which can be traced to the sensory fibers of the phrenic nerve. The pain may be sharp and stabbing, heavy or cramping; it may be directly over the heart, the manubrium or on the left side of the neck or shoulder.

The physical findings show widening of the area of cardiac dullness, and an X-ray will show widening and obliteration of the normal heart shadow. Change of position from the sitting to the recumbent posture will evidence a shifting of the area of dullness. A decrease in pulsation can be seen under the fluoroscope. Signs of lung compression at the angle of the left scapula, such as bronchial breathing and dullness, are usually present. A friction rub may or may not be heard. Removal of fluid for smear and animal inoculation will aid in the diagnosis. A fluid which is hemorrhagic or purulent should make one suspect tuberculosis. The quantity usually varies from 150 to 1,000 c.c. and is light amber to greenish-yellow in color.

The course of the disease is from several weeks to months, with development of circulatory symptoms, emaciation, continued fever, anorexia and signs of the concomitant tuberculosis. The prognosis is reasonably good.

Treatment in the main consists of strict bed rest and careful dietetic supervision. The results of aspiration alone are not encouraging and if the fluid is moderate and causing no discomfort thoracentesis is not indicated. When the heart shows signs of being crowded, pneumopericardium can be used and good results have been reported by several workers, such as Meyer, Castex, Wenckeboch and Oppenheimer. The use of air and lipiodol is recomemnded by W. Ackermann with report of good results. Lemaire also reports the use of lipiodol injection favorably. Pericardotomy has been practiced and brings about a drainage into the spaces surrounding the pericardium. Without surgery, resorption takes place gradually and can be promoted by the use of diuretics.

CASE REPORT

J. S., a male negro boy, aged 8, was admitted to St. Mary's Hospital, Duluth, October 26, 1929, with sore throat, cough, pain in the chest, loss of appetite and fever 100.8. These symptoms had been present for 10 days.

Past History: Negative.

Family History: Mother living and well. Father died of pulmonary tuberculosis; one sister at a sanatorium, with childhood tuberculosis; one brother, aged 4, died of tuberculous meningitis. Paternal aunt died of pulmonary tuberculosis.

Physical Examination: Negative except for chest, which shows impaired resonance over the left lower chest and axilla and showers of râles at both bases. Heart tremendously enlarged to percussion and a friction-rub present.

Laboratory Study: X-ray taken showed heart tremendously enlarged with definite pericardial effusion. No definite evidence of tuberculosis present.

Urine normal.

Sputum negative on seven occasions for tubercle bacilli.

Blood: R.B.C. 3,500,000; W.B.C. 5,800; Hgb. 70 per cent; calcium 17 and 15 mgm.

Electro-cardiogram: Inverted T wave.

Spinal fluid: Colloidal gold—111,222,000.

Course in Hospital: The patient's temperature remained around 101 and pulse 90 to 120 during his stay in the hospital. An attempt to aspirate the pericardium was made December 5, 1929, but no fluid was obtained.

On January 30, 1930, the von Pirquet test was positive and followed by a temperature of 103.

The patient had occasional short tetanic convulsions at seven to ten day intervals which would last about five minutes. A pericardial friction rub persisted during his stay. He was kept strictly in bed and given symptomatic treatment.

On June 24, 1931, the patient was transferred to Nopeming Sanatorium, where he was kept on bed-rest for eight months and then exercise was gradually stepped up so that now the child is attending school and goes to his meals. Sputum has always been negative for tubercle bacilli. The heart shadow has been closely followed by X-ray and a gradual return of the heart to normal size has taken place, exposing at its left upper edge a parenchymal lesion, undoubtedly tuberculous in nature.

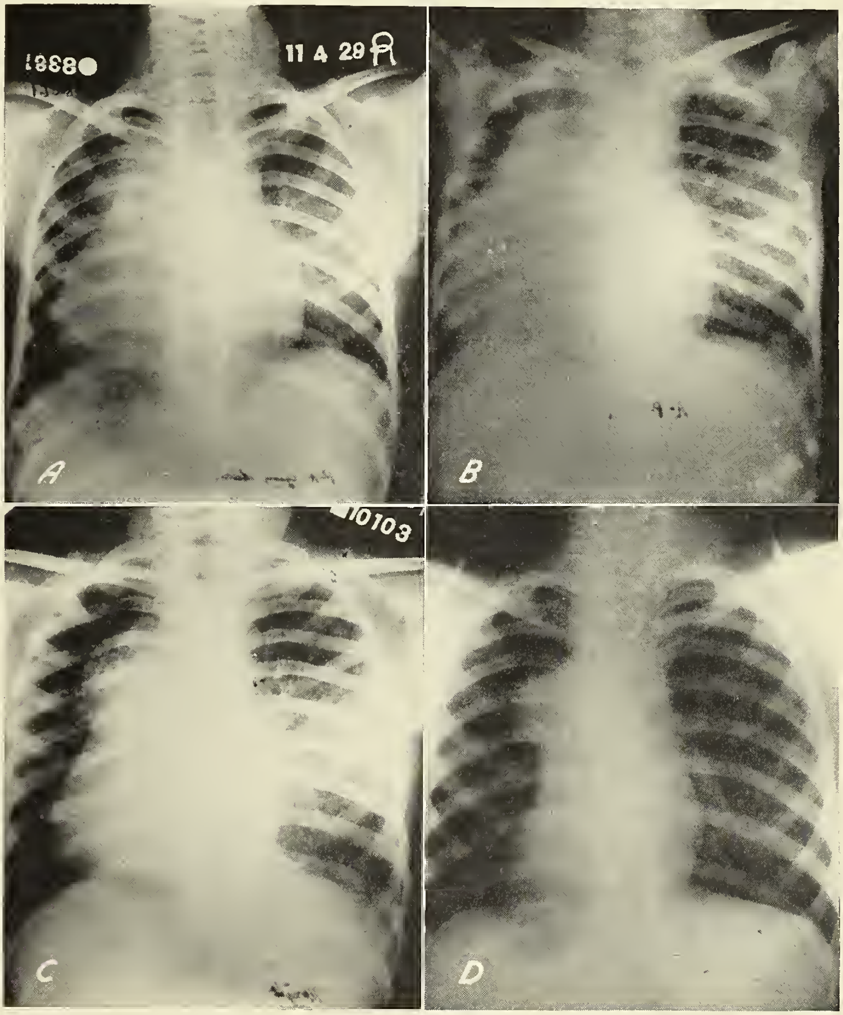


Fig. 1. X-rays showing progress in size of heart. View A was taken November 4, 1929; B, January 1, 1930; C, June 11, 1930; and D, June 6, 1931. View D shows tuberculous infiltration at the left upper edge of the hilus.

The patient had two or three convulsive seizures after admission to the Sanatorium, the last occurring in October, 1930.

Temperature and pulse have returned practically to normal. Treatment has been symptomatic, plus rest, diet and sun therapy.

In view of the suggestive history and findings in this case plus the adjacent tuberculous lesion in the lung parenchyma and absence of other etiologic factors, we feel sure that this is a case of tuberculous pericarditis even though no fluid was obtained to clinch the diagnosis.

PRESIDENT'S LETTER

WE READ in various articles that the cost of medical care is beyond the means of the average man, meaning of the "white collar group" or of "the great middle class," and that something must be done about it. In many articles the inference is quite plain that the doctor is the chief cause of this. Just or unjust at this accusation may be, the medical profession must face it, and, if it is true, do the best possible to correct it or, if it is untrue, do the best possible to disprove it. A recent article in the American Medical Association Bulletin (December, 1931) by Dr A. H. Freiberg, past president of the Ohio State Medical Society, is well worth reading. Doctor Freiberg marvels, as many of us have, at the social philosophy that apparently insists that the chief relief needed by members of the great middle class is reduction of the cost of medical service for them and their families. No mention is made of, or remedies offered for, the really fundamental abuses affecting this group. What might be called socialization of medical service for the poor in one form or another, particularly in densely populated areas, is already accomplished. Socialization of medicine beyond that point is contrary to the fundamentally sound economic structure on which our country has developed and is not in accord with American ideals. Dr. E. S. Judd, president of the American Medical Association, in an article in the same issue of the American Medical Association Bulletin as that in which Doctor Freiberg's article appeared, pointed out that there are sound reasons for believing that the so-called high cost of medical care is over-rated, and that, owing to its elasticity, the cost of ill-health is in reality pretty well within control of the combined efforts of the patient and his physician in most instances. In the recent period of general inflation, hospital costs and the wants of the individual patient soared along with everything else.

It is only natural that a difference of opinion as to how medicosocial problems are to be met should develop between those who make their living in the actual practice of medicine and those engaged in preventive medicine, such as full time health officers. There never has been any difference of opinion as to the desirability of education in public health, of the institution of means to prevent disease, and so forth. The medical profession is and always has been solidly behind such measures.

However, this difference of opinion has been misinterpreted by many laymen to mean that the attitude of the mass of our profession toward these problems is one of indifference, and that the credit for delivering to the public the benefits of medical advance must be given to the social worker. We know this is not true; nevertheless, many have such an impression, and some of those who have it are truly friendly to the medical profession. The only answer is for organized medicine, through its representatives, to take the lead in all matters pertaining to public health.

Freiberg also aptly pointed out that, owing to the large number of measures which are directly or indirectly of importance to our profession and which are proposed for enactment in our legislative bodies, it has become necessary for organized medicine to be represented at every legislative assembly in the United States. This activity, not agreeable so far as it smacks of lobbying, may be rendered less obnoxious to us if we regard it as our fulfilling of a trust reposed in us, because the special knowledge we possess marks us as best fitted to know what is to the best interest of the public in matters pertaining to health. There is no evidence that this trust has been abused.

M. S. Henderson.

President,
Minnesota State Medical Association.

CHOICE OF ANESTHETIC

The ideal anesthetic should entirely obviate pain, should be attended by no mortality or deleterious effects on any organ of the body and should be unaccompanied by complications. Have we such an anesthetic? No.

The discovery of the anesthetic properties of both ether and chloroform about the middle of the nineteenth century was a great boon to humanity. Chloroform, being pleasanter to take and requiring a less amount, soon became the more popular of the two. In recent years it came to be recognized generally that chloroform is definitely more dangerous than ether, not only because of the immediate mortality but because of late toxic effects.

Because of the definite disadvantages accompanying the use of ether—its explosibility, postoperative vomiting and occasional pulmonary complications—repeated efforts have been made to develop substitutes. Nitrous oxide has proven a good substitute for short operations but is decidedly more dangerous for prolonged anesthesia. Ethylene gas, a recent development, though possessing a less pleasant odor, is easier to inhale and is much less likely to be followed by vomiting. If it were not for the fact that it produces less relaxation and is also highly explosive, ethylene would come close to being the perfect inhalation anesthetic. Rightly it has largely supplanted ether.

Local anesthesia fills the bill for many surgical needs. Novocain, the drug most commonly used, is suitable for a great number of operations, especially where inhalation anesthesia is undesirable. Undoubtedly enthusiasm has led to an overextension of its field of usefulness. This has been particularly in evidence in the German clinics. Enthusiasts with well developed technic which includes nerve blocking have known no limit in their successful use of local anesthesia, but there is no question that for the general surgeon its use should be restricted.

The various more recent substitutes, scopolamine and morphine hypodermically, avertin rectally, and amytal intravenously, have in common the objection that an overdose leaves the surgeon helpless. The mortality rates with these drugs are higher and for this reason they should not and have not come into general use.

The rapid adoption of spinal anesthesia is a contradiction of the oft heard accusation that the medical profession is averse to the adoption of new methods. There are those who feel that spinal anesthesia has had too general adoption. The advantage of the resultant relaxation, greater than with any other anesthetic, is more than counterbalanced by the high mortality, the lack of control of the anesthetic action, the frequency of post-anesthesia headache and lowering of blood pressure which at times is alarming. The attending mortality is distinctly high and for this reason alone spinal anesthesia should be used in a restricted field by those who are well acquainted with the technic of administration.

In selecting an anesthetic, the patient deserves the entire consideration. His safety and comfort are of prime importance. Psychic trauma is real. Overenthusiasm for an anesthetic in preference to all others is a mistake. Selection should be made to suit the indications in the individual case.

SEVERE ANEMIAS—RECENT LITERATURE

Few medical subjects provide greater present interest than the field of hematology. Those who have followed the ideas and attitudes of laboratorians and clinicians for the past twenty-five years realize that the morphologists and symptomatologists have had their research and clinical innings in repeated sequences, where the game has been lively and the scoring heavy. Unit or dual origins of blood elements continue to hold less attention than the Hippocratic background of constitution, in which the bone marrow has offered the fundamental position.

The clinician who fails to sense this is likely to be lost while guiding himself by such supposedly "fixed harbor lights" as minus indices or attention to uncorrelated blood counts. For those who do not see a fair number of anemic patients the confusion in the literature is accentuated, because it is apparent that the atypical cases soon come to assume such frequency that they ultimately establish the basic principles involved rather than the "regular run of the mill."

The temptation is great (as has been shown by Watkins) to assume a pseudo- or pre-pernicious anemia category: individuals with low counts, achlorhydrias and hypochromasia. Dameshek[1] has recently discussed this type, but finds little difference in the "hyperplastic (sternal) bone marrow" except as to the microcytic or megalocytic cellular elements.

With this slight differentiation he might well infer that these severe hypochromasic anemias could well be a type or earlier stage of true Addisonian anemia. In any case, they seem to need iron, either because of faulty digestion and assimilation, with inadequate hemoglobin synthesis, or from other unknown factors; in any case, the present day heroic iron dosages are firmly established. This would obviously run counter to the older attitude concerning the futility of iron exhibition in pernicious anemia, because the tissues are often suffused with iron, the apparent result of extreme blood destruction. All the studies in tissue therapy (liver, stomach wall, kidney, etc.) concentrate upon the general idea that in active pernicious anemia the immature blood cells extruded into the circulation are either physiologically insufficient or defenseless against physiological removal; hence, it might be that a severe anemia in the hypochromasic stage might call for iron; if it should extend into the state of perverted and muddled bone marrow capacity, the resultant blood destruction might bring other needs to the foreground, exclusive of iron.

In this order Cassel,[2] with his ingenious feeding experiments, gradually draws our attention to the vital products eliminated or synthesized in the gastric wall. It would appear that his studies will greatly help to allocate to the clinical findings of degree and type of gastric secretion the true and accurate position of this vital phenomenon in the anemias as a whole. Whatever his "intrinsic factor" proves to be, it now seems to be entirely independent of the other measurable substances known to exist in normal gastric juice. While this is a qualitative factor, the "extrinsic" feature is quantitative, and has to do with the amount of meat or other protein upon which the intrinsic substance has had its action.

It is to be hoped that the unnecessary technicalities may be gradually disposed of and we may come to have a wholesome appreciation of the manner in which the gastrointestinal tract on the one hand balances off with pabulum and stimuli the effectiveness of the bone marrow system; likewise, the manner in which secretion as a whole is determined or inhibited by the central nervous system. In any case, the circulating blood may or may not furnish the criteria which indicate correctly how these other vital functions are carrying on. There would appear to be sufficient indication to justify an intensive drive to better understand bone marrow. Does any one think he knows much about it? It is time to proceed from a simple static attitude to an attempt to fathom its dynamic possibilities.

MEDICAL HISTORY

The recent visit to the Twin Cities of Professor Henry E. Sigerist, Director of the Institute of Medical History, Leipzig University, has emphasized to the professional as well as to the lay mind the vital necessity of a philosophical background for anyone who is to attain proper eminence in the field of medicine. Dr. Sigerist spoke before the American Historical Association and was a guest at the winter meeting of COS-CNIDUS, a society which has for its object the congenial pursuit of the cultural and historic aspects of medicine. The reasons prompting the desire of the few to study the history of medicine should also stimulate the many to thought along these lines.

We are today, in this century, perhaps very near the crest of a golden age of scientific and mechanical achievement. There has been so much of factual and material addition to our lives, and in so short a space of time, that one stands a little dizzily upon the heights achieved with our hands, heights not, as yet, entirely realized by our imaginations. The advance has been so rapid, especially in science, that we have almost broken with the past. Our giant stature has dwarfed for us the preceding centuries, partly has made us forget our inherited debt and creates an illusion of self-sufficiency that is, perhaps, a little vulgar. Such a condition stirs memory and rouses a sense of danger so that once more it seems as if, in the words of Sir Thomas Browne, " 'Tis opportune to look back upon old times and contemplate our forefathers."

Four hundred years ago science began to divorce itself from the church, up to that time the accepted vehicle of all cultural endeavor. Under its influence thought had become inelastic, dogmatic and altogether removed from practical living. The method of science, dispassionate inquiry into unrelated facts, felt more and more the necessity of separating itself from the rigid formulas of scholasticism, since the latter threatened to blot out its very existence. One of the first effects, as the breach grew wider, was an increasing decentralization of thought and deed. Authority and unity of command meant a stifling of thought, so that every effort was made to escape this on the one hand and, on the other, to strengthen the freedom of action of the individual. In addition, structural thinking was cast overboard, and the experimental method alone came to dominate the field.

The culmination of the movement was seen in the early years of the present century, when the civilized world presented the picture of thousands of widely spread laboratories and clinics in which innumerable investigators were engaged in piling up, with unflagging patience, a staggering array of unrelated facts. At the same time the reaction against authority had reached its height, so that one beheld the spectacle of men who, in contiguous laboratories, and working on the same problem, often resolutely refused to concede even a tittle of merit to each others' efforts. Contempt for precedent and organization led inevitably to this result. In divorcing himself from the past, in working alone, many an investigator and clinician paid the inevitable price of such isolation. His world of mental vision narrowed, healthy skepticism became suspicion, and personal experience, lacking the leaven of a wider culture, instead of serving truth too often resulted in mere prejudice and provincial ignorance. John Hunter's dictum, "Don't think, try," was followed with a thoroughness that unfortunately left little to be desired. Our library shelves sag with the results of this furious pursuit of facts, and while the trying thousands yearly add to the indigestible load, the occasional Pasteur, thinking as well as trying, creates magic. Together with the very real achievements of the few there has thus grown up a great army of little people who, unchastened by the discipline of thought or contemplation of the past, threaten the very science they seek to serve.

Thus we begin to realize that in overthrowing the already accomplished instrument of philosophic method we have, so to speak, thrown away the child with the bath water. We are surrounded with data innumerable and appear unable to synthesize them. The danger is real and the cry for correlation arises from more than one great university. To a large extent, present day investigators and clinicians of the highest type have seen the problem and are facing it. Obviously there are many roads of approach to its solution and of these that of historic method is not the least.

To this end, then, among others, the study of the history of medicine serves splendidly and in its pursuit one may hope not only to relish great minds and great accomplishments, but also, perhaps, to achieve a little humility.

H. LONGSTREET TAYLOR

Some in an early stage of their medical careers have a vision of a goal worth while. Too often distractions cause a letting up in endeavor or a diversion from the chosen path.

Longstreet Taylor became Dr. Longstreet Taylor in 1882, by coincidence the same year that the German physician Dr. Robert Koch made his outstanding contribution to medical science—the discovery of the tubercle bacillus. Dr. Taylor was content with nothing less than a year spent in Berlin under Dr. Koch.

Upon his arrival in Saint Paul in 1893 Dr. Taylor began devoting his energies to the fight against the scourge of tuberculosis, especially in his city and state. Article after article on the subject appeared in the local journal—the Northwestern Lancet. He toured the state in an effort to arouse public interest. He appeared repeatedly before the state legislature. He was the pioneer and the leader in the hard up-hill fight in those earlier days when both the public and the medical profession had to be convinced of the necessity of a departure in methods of treatment of tuberculosis if success was to be achieved. Few knew of his expenditure of energy and time and even of his private means in the pursuit of his main objective—the elimination of tuberculosis.

It was not until the year 1918 that the statistics in this state began to indicate that the foe was beginning to yield. Dr. Taylor lived to see the mortality rate of tuberculosis more than cut in half. With a tireless carrying-on of the work he started there is no reason why this still dreaded disease cannot be practically eliminated just as other similar scourges have.

Dr. Taylor aroused the antipathy of some physicians by his insistence on the necessity of public care of those afflicted with tuberculosis. Experience has vindicated the correctness of his viewpoint. Many were his friends both within and without the profession and many feel the real loss of his going.

MISCELLANEOUS

SOCIAL INSURANCE IS CONTRARY TO THE FUNDAMENTAL PRINCIPLES OF DEMOCRATIC GOVERNMENT*

Edward H. Ochsner, M.D.
Chicago

All forms of Social Insurance are contrary to the spirit of democratic government. They destroy individual incentive, initiative and self reliance. They substitute paternalistic control for independence of thought and action. We pride and congratulate ourselves on living under a democratic form of government but most of us fail to realize that we are slowly but surely drifting away from the true democratic spirit in government —that we are gradually substituting a hybrid form of government, a cross between bureaucracy and socialism. Personally, I am a firm believer in democracy and believe that many of our present ills are the direct result of already having deviated too far from the fundamental principles of democracy.

Individual responsibility is the foundation of democratic government. If a nation does not educate its citizens to individual responsibility, it will soon have no one capable of assuming public responsibility. Slowly through the ages the common man has risen from chattel slavery and serfdom to independence, freedom and personal liberty, and now some well-meaning but misguided people want to undo all this. They want to enslave him again, making him in fact a bondsman of the state. Organized society is forever forging new chains with which to shackle the free development of its members. It is forever meddling with the private affairs of its citizens. One of the best illustrations of this statement is found in a recent survey of the Citizen' Bureau of Milwaukee which found that that city is engaged in approximately three hundred different functions, one-fifth of which have been added during the last sixteen years. Milwaukee is no worse in this respect than many other cities in this country. Add to this the activities of the county, state and federal governments, and we find an explanation of the following fact: "In a period in which the population of the United States has increased ten per cent the number of persons holding civil office has increased forty per cent and the amount paid in salaries has increased one hundred and fifty per cent." Thirty years ago one person in every forty-five was in government employ while now one in every twelve is so employed.

---

*One of a series of articles appearing in state medical journals on various phases of socialized medicine.

"It is a profound mystery why the people of the present generation should so violently run after the very things their forefathers so violently ran away from in 1776. One of the chief indictments of King George set forth in the Declaration of Independence reads: 'He has erected a multitude of new offices and sent hither swarms of officers to harass our people and eat out their substance.' "

In a recent article, Dr. Harry Emerson Fosdick makes a statement that seems particularly suitable in this connection. He said, "Many of those in society who are dissatisfied with present conditions know what they want to get away from, but they do not know whither they are going." I would add, "nor do they seem to have any clear idea as to what they want." Before we adopt new laws we should make reasonably sure that such laws will not introduce new and greater evils than they are expected to cure, that they can actually be enforced, and that they are not likely to be abused in their administration.

A far reaching innovation such as Social Insurance must be viewed from many angles. We must consider its effect upon the general public, the insured, the employer, and the medical and dental professions.

If we are deliberately trying to get away from the democratic form of government, having a definite objective in view, and if we are reasonably certain that the goal for which we are headed is worth while and is going to result in general social and economic betterment, an experiment with Social Insurance might be justified, but, even then, it is well to carefully weigh and consider what the wise founders of our government had to say on this important subject. I quote from the Declaration of Independence, "Prudence, indeed, would dictate that government long established should not be changed for light and transient reasons." If we as a nation are just aimlessly drifting, as we seem to be, we are almost sure to get into serious trouble. We believe that we shall be able to show conclusively, in future articles, that in those countries in which it has had prolonged and extensive trial it actually has had serious consequences. These latter problems will be taken up in subsequent articles.

CULTIVATION OF "COMMON COLD" VIRUS

The growing conviction that "common colds" are not due to any micro-organism thus far included in commercial vaccines, but to an unknown filtrable virus or group of viruses, is strengthened by the currently reported successful cultivation of bacteria-free pathogenic nasal filtrates. The work indicates conclusively that the filtrable agent associated with "common colds" multiplies or is multiplied in the embryonic tissue medium. (Jour. A. M. A., August 15, 1931, p. 466.)

OBITUARY

John Benson Brimhall

1862-1931

Dr. J. B. Brimhall, Saint Paul, was born July 4, 1862, on a farm located now within the city limits of Saint Paul between Randolph and St. Clair, Snelling and Hamline Avenues. Here his parents had moved in 1851.

After attending the public schools in Saint Paul he enrolled in 1886 in the St. Paul Medical College located on West Ninth Street. Upon its discontinuance the next year he entered the University of Pennsylvania medical school, where he graduated in 1890. Upon graduation he opened an office in the Moore Building at Seven Corners, Saint Paul, where he was associated with his friend, Dr. Arthur J. Gillette, for twenty-three years.

During the early years of his practice he was assistant city physician, taught in the Hamline University Medical School, and later was on the teaching staff of the University Medical School. Staff membership included St. Joseph's and St. Luke's hospitals among others.

On January 26, 1891, Dr. Brimhall became a member of the Ramsey County Medical Society and retained his membership in the county, state, and national organizations until his death December 21, 1931.

He was Executive Secretary of the State Board of Medical Examiners from 1897 to 1901 and during this period devoted considerable time to the Legislature in the interests of legislation for the betterment of medical practice.

On September 24, 1890, Dr. Brimhall married Miss Nellie Nabon. A son and three daughters were born before Mrs. Brimhall's death in 1903. Later he married Mrs. Laura Matthews, who, with his three daughters, Mrs. Carlton C. Brainard, St. Paul, Mrs. Oswin Reeves, Minneapolis, and Mrs. Frank Daniels, Long Lake, Minnesota, and one step-daughter, Mrs. Colin MacDonald, St. Paul, survive him.

As a statement in his county society records: "Quiet and unassuming in nature, his record will not be found on the pages of medical journals or textbooks but is graven deeply in the hearts of his friends, and his patients were his friends."

Henry Longstreet Taylor

1857-1932

Dr. H. L. Taylor, Saint Paul, was born in Cincinnati, Ohio, August 14, 1857, and died at his home January 2, 1932, at the age of 74. He attended Haverford College at Haverford, Pennsylvania, and received his medical degree from the College of Ohio, now the University of Cincinnati, in 1882.

It was in 1882 that Dr. Robert Koch discovered the tubercle bacillus and the subject so intrigued Dr. Taylor that he went to Berlin, where he spent a year working with Dr. Koch. The next two years he spent at Prague, and returned to practice in Cincinnati. Poor health necessitated his moving to Asheville, North Carolina, where he practiced for four years, coming to Saint Paul in 1893.

Dr. Taylor joined the Ramsey County Medical Society May 1, 1893, and the same month read the first of a number of papers before the society on the subject of tuberculosis. He became secretary of his county society in 1894 and on retiring in 1895 made a plea for the founding of a medical reference library. Dr. Taylor was appointed on the committee which led to the forming of a library association and eventually to the taking over of the library by the society in 1897.

Interested in tuberculosis from the beginning of his medical career, on arriving in Minnesota Dr. Taylor began a publicity campaign in the interest of antituberculosis fight, making addresses in various parts of the state. His untiring efforts were largely responsible for the authorization of a state sanatorium in 1903 which was opened at Walker in 1907. His private tuberculosis sanatorium at Pokegama, opened in 1905, has the distinction of being the first sanatorium in the state.

In 1906 the Association for the Prevention of Tuberculosis was formed as a private undertaking in Saint Paul and a county tuberculosis camp was established in 1910 at Cuenca on the shore of Lake Owasso. On this property the county Preventorium was later established in 1915.

In 1913 the legislature passed the County Sanatorium Bill which provided state subsidy for county sanatoria. It was not until 1918 that the mortality statistics showed the results of the fight against tuberculosis. But Dr. Taylor lived to see the death rate from tuberculosis more than halved.

Dr. Taylor was one of the members of the first editing and publishing committee of MINNESOTA MEDICINE and served until 1923, when he was appointed Councilor of the State Association. He was president of the Minnesota Public Health Association from 1924 to 1927 and president of the National Tuberculosis Association in 1928. The Trudeau society of Minnesota honored him with a dinner at the time of his presidency in 1926. In March, 1928, a dinner sponsored by the Lymanhurst medical staff was tendered him at the New Nicollet Hotel in Minneapolis.

At the time of his death Dr. Taylor was chairman of the Children's Preventorium and the Pokegama Sanatorium, a member of the Minnesota Club and the Minnesota Academy of Medicine. Surviving him are his widow and three children, Henry L., Jr., Laura and Louise Nicolich of New York.

Dr. Dudley C. Frise

1887-1932

Dr. Dudley C. Frise, of Minneapolis, died unexpectedly Sunday morning, January 10, 1932, while resting after playing two chukkers of polo at Fort Snelling riding hall. Death was due to heart disease.

Dr. Frise had lived in Minneapolis since his graduation from the medical college of Northwestern university in 1904. Previously he had attended the University of Minnesota, where he was the youngest student ever to enter the school of pharmacy. He was born in Hamilton, N. D., in 1887.

Active in civic affairs, Dr. Frise was a member of the Minneapolis Athletic club, president of the Exchange club, a director of the Salvation Army, and the Boy Scout advisory council. He was also a member of the Minneapolis Red Cross chapter, and the Fort Snelling Polo club.

Surviving him are his wife; a brother, Melvin Skews Frise of Minneapolis; a sister, Mrs. T. Arthur Prichard, and two children by a previous marriage, Richard and Geraldine.

Dr. F. G. Watson

1871-1932

Dr. F. G. Watson, 60, a resident of Nobles county for more than twenty years, died at his home in Worthington, Minn., Monday, January 11, 1932, following an illness of nearly two years.

After coming to Rushmore in 1910 Dr. Watson practiced medicine continuously there and in Worthington until January 14, 1930, when he was stricken with a heart attack during an operation. He was then forced to retire and had been in a serious condition since.

Frederick Goodwin Watson was born in Ireland, December 23, 1871. He came with his parents to New York in 1884 and after spending a summer in New York, they moved to western Canada, locating on a farm 125 miles west of Winnipeg. He took up the study of pharmacy in 1890, attending the University of Manitoba. In 1896 he came to Wood Lake, where he opened a drug store. During McKinley's administration he was postmaster there.

In the fall of 1898 Dr. Watson took up the study of medicine at Hamline university. After completing the medical course there he located at Clarkfield, where he practiced medicine and conducted a drug store.

In 1910 he moved to Rushmore and remained there until 1918, when he came to Worthington, associating himself with Dr. B. O. Mork. They operated the old Humiston hospital under the name of Mork & Watson. In 1920 they organized the Worthington Clinic. Dr. Watson was active in interesting other men in the Clinic and in the construction of the office building.

In 1921 Dr. Watson took post-graduate work in Chicago and at Tulane university in New Orleans.

He married Miss Isabelle A. Tibbils on September 1, 1897, and to them five children were born: Horace Percy Watson of Worthington, Dr. Leo Watson of Parkersburg, Ia., Dr. Sidney J. Watson of Worthington, Donald G. Watson of Worthington and Mrs. Bernice Ann Maxwell of Sioux Falls. The children and Mrs. Watson survive, as do also one sister, Mrs. R. S. Butchart of Greensboro, N. C., and two brothers, James Watson of Minneapolis and Ernest Watson of Wauwatosa, Wis.

OF GENERAL INTEREST

The Brigham hospital at Watkins, Minnesota, has been reopened for patients due to the numerous calls for hospital service in the community. Dr. F. T. Brigham is in charge.

Dr. C. Oliver Heimdal, formerly a fellow in surgery at the Mayo Clinic, was elected secretary and treasurer of the Aurora (Illinois) Medical Society at their last meeting.

Dr. Byron O. Mork, Jr., graduate of the University of Minnesota Medical School in 1930, spent the past year as interne at the Receiving Hospital, Detroit, Michigan, and is now associated in practice with the Worthington Clinic, Worthington, Minn.

Paul Fesler, superintendent of University Hospital, Minneapolis, has accepted the superintendency of Wesley Hospital, Chicago, affiliated with Northwestern University. Appointment of a successor to Mr. Fesler has not yet been made.

Dr. Louis B. Wilson, Director of the Mayo Foundation of the University of Minnesota, was recently elected President of the Association of the American Medical Colleges. More recently also he has been elected National President for two years of the Society of the Sigma Xi.

The John Phillips Memorial Prize of the American College of Surgeons for 1931 consisting of the sum of $1,500 has been awarded to Dr. O. T. Avery of the Rockefeller Institute, New York City, for his series of studies on the pneumococcus. The award will be made at the meeting of the College at San Francisco in April.

Dr. B. F. Van Valkenburg, Long Prairie, was elected president of the Minnesota State Sanitary Conference at its annual convention in December. Dr. W. H. Valentine, Tracy, was named vice president; Dr. A. J. Chesley, Minnesota State Board of Health, secretary-treasurer. Drs. George Wattam, Warren, and H. M. Workman, Tracy, were elected life members.

Dr. Edward Bratrud of the Bratrud Clinic, Thief River Falls, has recently added to his Staff Dr. Lucien G. Culver, recently associated with Drs. Wheeler, Larson, and Wold at St. Paul in the practice of Eye, Ear, Nose and Throat; also Dr. Charles W. Froats, who recently completed a two years' Fellowship in Gynecology and Obstetrics at the University of Minnesota.

The fourth annual high school Gorgas Essay Contest for high school juniors and seniors, sponsored by the Gorgas Memorial Institute, Washington, D. C., will open February 7 and close March 15. The subject of the contest is "Mosquitoes, Their Danger As a Menace to Health and the Importance of Their Control." High school winners will qualify in the State Contest, the prize to be $10 in cash, and state winners will be entitled to enter the National contest, with a prize of $500 in cash and a travel allowance of $200 to Washington. Detailed information may be obtained by writing to Gorgas Memorial Institute, 1331 G Street N. W., Washington, D. C.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

CANCER "SPECIALIST" LEAVES STATE FOLLOWING $1,000.00 FINE

State of Minnesota *vs.* Boyd T. Williams

On Saturday, December 19, 1931, Boyd T. Williams, who for twenty years has maintained a cancer sanitarium in Minneapolis and in recent years at 525 University Ave. S. E., was sentenced to pay a fine of $1,000.00 or to serve one year in the Workhouse in the City of Minneapolis, by the Honorable Arthur W. Selover, Judge of the District Court of Hennepin County. Williams paid the fine.

Defendant had been under arrest for some time following the filing of a complaint against him by Mr. Brist, representing the State Board of Medical Examiners. Williams was charged with practicing healing without a Basic Science Certificate. When Williams was brought before the Court to receive his sentence he informed the Court that he had closed his place and had removed his sanitarium to Hudson, Wisconsin, which fact has been verified by the State Board of Medical Examiners.

This is the third time that Williams has been convicted of violating the Medical Laws of this State since the enactment of the Basic Science Law in 1927. In 1913 Williams was fined $50.00 by the Municipal Court of Minneapolis for practicing medicine without a license. In 1928 he paid a $100.00 fine for practicing without a Basic Science Certificate. In 1929 he paid a fine of $250.00 for a like offense.

The closing of this case and the removal of the defendant to Hudson, Wisconsin, should mark the end of Williams' practicing in Minnesota without a license.

ANNUAL SECRETARIES CONFERENCE

A record making attendance of close to one hundred physicians and others registered for the Annual Secretaries Conference of the Minnesota State Medical Association, Saturday, January 23, at the St. Paul Hotel in St. Paul.

The program, scheduled to last until 4 P. M., was prolonged until 6 P. M. to give time for discussion.

The three major events of the morning program included discussions of fee collection methods led by Mr. Albert Wilson of St. Paul; a recital of the work of the joint coöperating committees of the Minnesota Editorial and the Minnesota State Medical Association by Mr. Roy J. Dunlap, Managing Editor of the St. Paul Pioneer Press and Dispatch, and J. A. Watson, chairman of the Medical Association Committee, Minneapolis, and a symposium on Medical Care of the Poor under the chairmanship of Dr. Theodore Sweetser, Minneapolis, chairman of the State Health Relations Committee. W. C. Andrews, Frederic, Wisconsin, president of the Polk County Medical Society; Mr. Vernon D. Blank, Des Moines, general manager of the Iowa State Medical Society, and Dr. Harold M. Camp, Monmouth, Ill., secretary of the Illinois State Medical Society, reported on the systems in use in their respective states. The Hon. Henry Benson, Attorney General, commented upon possibilities of introduction into Minnesota of the contract system in use in Iowa and elsewhere for care of the poor.

The luncheon address on the subject "The County Society Turns the Tide against State Medicine," was made by Mr. H. Van Y. Caldwell, Cleveland, executive secretary of the Cleveland Academy of Medicine, with a discussion by Mr. Theodore Wiprud, executive secretary, Milwaukee County Medical Society.

The afternoon program was devoted exclusively to Periodic Medical Examinations and Medical and Hospital Care for Veterans, the latter occupying the major portion of the time.

Dr. C. A. Hensel, St. Paul; Dr. C. B. Wright, Minneapolis, and Dr. M. C. Piper, Rochester, discussed advisable extent and methods of public education for the periodic health examination.

Dr. Otho A. Fiedler, Sheboygan, Wis., president of the Wisconsin State Medical Society, outlined the history of the Shoulders Resolution for substitution of disability insurance for further government hospital building for veterans. A two-hour discussion of the situation followed, led by Dr. C. B. Wright, chairman of the Legislative Committee of the American Medical Association; Mr. Paul Fessler, president of the American Hospital Association; Dr. Herman Johnson, chairman of the Committee on Public Policy and Legislation; Dr. N. G. Mortenson, formerly president of the Forty and Eighter; Dr. James J. Morrow, former Vice Commander of Minnesota American Legion, and Dr. H. R. Tregilgas, South St. Paul.

Many out-of-state visitors to the conference remained to take part in the Annual Northwest Regional Medical Conference which met informally Sunday, January 24, at the St. Paul Hotel. Nine states were represented at this conference and more than fifty were registered in attendance in the course of the day. Sessions began with breakfast meeting at 8 A. M. and continued until 5:30 in the afternoon.

Among those who attended the meeting were Dr. Otho A. Fiedler, Sheboygan, Wis., president of the Wisconsin State Medical Society and retiring president of the Conference; Mr. Vernon D. Blank, general manager of the Iowa State Medical Society, secretary of the Conference; John L. Marker, Davenport, Iowa; Dr. L. R. Woodward, Mason City, Iowa; Dr. D. J. Glomset, Des Moines; Dr. R. W. Fouts, Omaha, Neb.; Dr. B. F. Bailey, Lincoln, Neb.; Dr. George Crownhart, Madison, Wis.; Dr. Earl Whedon, Sheridan, Wyo.; Dr. Harold M. Camp, Monmouth, Ill.; Dr. R. G. Leland, Chicago; Dr. J. F. D. Cook, Langford, S. Dak.; Mr. H. Van Y. Caldwell, Cleveland, Ohio, and Mr. Theodore Wiprud, Milwaukee.

Minnesota representatives who attended the conference were Dr. E. A. Meyerding, St. Paul; Dr. C. B. Wright, Minneapolis; Dr. M. S. Henderson, Rochester; Dr. W. F. Braasch, Rochester; Dr. Herman Johnson, Dawson; Dr. H. M. Workman, Tracy; Dr. George Earl, St. Paul.

Medical economics, care of the indigent, lay health education methods and the budgeting of medical publications were discussed at length in the course of the day.

Dr. Cook was elected president of the Conference to succeed Dr. Fiedler. Mr. Blank was re-elected secretary. St. Paul was chosen again as next year's meeting place.

FOODS

The following products have been accepted by the Committee on Foods of the Council on Pharmacy and Chemistry of the American Medical Association for inclusion in Accepted Foods:

Del Maiz Niblets Brand (Minnesota Valley Canning Company, Le Sueur, Minn.).—A "vacuum" packed canned whole-kernel corn containing no added salt or sugar and very little added water. It is claimed to be the canned whole kernels of a special breed of corn packed in vacuum to protect the flavor and processed with only a small amount of added water to retain the form of the original kernels.

Green Giant Brand Great Big Tender Peas (Minnesota Valley Canning Company, LeSueur, Minn.).—Canned ungraded "fancy quality" Green Giant variety peas sweetened with sugar and seasoned with salt. This product is claimed to make an appetizing and easily digestible purée for infants.

SMACO (200) Whole Milk Sterilized (S. M. A. Corporation, Cleveland, Ohio).—A canned sterilized homogenized whole milk. It is recommended for all uses of whole milk and especially for infant feeding. (Jour. A. M. A., September 12, 1931, p. 780.)

Harvest Bread (Hecht's) (Hecht's Bakery, Bristol, Tenn.).—A white bread made by the sponge dough method. It is claimed to be a bread of good quality. (Jour. A. M. A., September 19, 1931, p. 853.)

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of February will be as follows:

February 3—Personal Hygiene—Food Selection.
February 10—Buerger's Disease.
February 17—Prevention of Goiter.
February 24—Is Cancer Inherited?

AMERICAN COLLEGE OF PHYSICIANS

The sixteenth annual Clinical Session will meet in San Francisco the week of April 4, 1932. General Sessions will be held each afternoon, Monday to Friday inclusive and Monday and Tuesday evenings. Clinics and demonstrations will occupy the mornings.

The subjects to be emphasized will be the recent contributions to the fields of arteriosclerosis, hypertension, nephritis, the autonomic nervous system, gastrointestinal physiology, hematology, and diseases peculiar to the Rocky Mountain and Coast territory.

All physicians in good standing are invited to attend. The guest fee of $15.00 includes one year's subscription to the Annals of Internal Medicine, the official journal of the college. Entertainment will be provided by the local committee for members of the families of those who attend.

Dr. S. Marx White, Minneapolis, is president of the organization this year and Dr. George Morris Piersol, Philadelphia, is secretary-general.

STATE MEETING

A program full of novelties and innovations is in process of completion for the 79th meeting of the Minnesota State Medical Association, which is, this year, to be held concurrently with the Minnesota Hospital Association at the new Saint Paul Auditorium, May 23, 24 and 25.

The Committee on Scientific Assembly wrestled for hours at its meeting January 16 at the Saint Paul Athletic club with the no less than 904 subjects suggested by the membership in an astonishingly large reponse to the questionnaire on scientific program sent out after the first meeting of the committee.

To comply with the largest possible number of these requests, the program is to be divided in an entirely unprecedented fashion. Table demonstrations for small groups will vie for time with the larger medical and surgical sectional meetings and the general meetings to be addressed by distinguished out-of-state guests.

In order to arrange discussion and demonstration of as many of the requested subjects as possible within the limited available time the committee has decided to hold table demonstrations during three program hours of the session: from 10 to 11 a. m. Tuesday, from 2 to 3 p. m. Tuesday, and from 10 to 11 a. m. Wednesday. Twenty of the best qualified men in the state will preside at these demonstrations, which will be carried on, round table fashion, for small interested groups in the large exhibit hall. The scientific and technical exhibits on display in the hall will afford ample material to interest those who do not attend the demonstrations. Subjects already suggested for these latter include fungi; Ascheim-Zondek test; electrocardiograph; undulant fever; allergic skin tests; urine typing of pneumonia; X-ray of juvenile tuberculosis; gallbladder technic; tuberculin test; Schick test; blood sugar; blood urea; albuminuria; arthritis skin test; cauterizing the cervix; brain model; localization; X-ray of ulcers; eye grounds.

The large joint sessions of the program will be confined to Monday afternoon, Monday evening and Tuesday and Wednesday from 11 to 12 a. m. and from 1 to 2 p. m.

Medical and surgical sections will meet separately Tuesday and Wednesday mornings from 8 until 10 a. m. The entire series will close Wednesday afternoon with a program of interesting short clinics, all to be held at the Auditorium.

Among the interesting guests speakers already secured by the committee for the meeting is Walter Sebening of the University of Frankfort, Frankfort on the Main, Germany. Dr. Sebening is completing six months of research on peptic ulcer at American medical centers, a subject on which he has done important work in Germany. He will report on his findings as one of the major program features of the meeting. Carter Wood, Columbia University, will talk on some phase, yet to be decided, of the cancer problem; Theodore M. Davis, Greenville, S. C., will explain a new and simple method of prostate resection with illustrative moving pictures and discussion by notable Minnesota urologists; Willis C. Campbell of Memphis, Tenn., will speak on some phase of industrial surgery, illustrating his talk with moving pictures; Ralph Major, Kansas City, will talk on hypertension.

For the Wednesday afternoon clinic the following subjects have been tentatively selected: blood, goiter, heart, kidney, epilepsy, diabetes, neurology, dermatology, mastoids, urology, poliomyelitis, eczema, periodic health examination.

Any members possessing moving pictures of scientific or technical interest to the medical profession are especially requested by Dr. W. A. O'Brien, chairman of the Committee on Scientific Exhibits, to write him about them, giving title, size and length. The films will be used to create a continuous moving picture show on the stage of the exhibit hall during the meeting.

Women of the Hospital Association have been extended an official invitation from the Women's Auxiliary of the medical association to meet with them during their two day annual meeting scheduled for Tuesday and Wednesday, May 24 and 25. An unusual and especially attractive number of social affairs is being arranged for the augmented meetings.

FRACTURE SYMPOSIUM

The Minneapolis Surgical Society and the Regional Sub-Committee of the Committee on Fractures of the American College of Surgeons will jointly conduct a symposium on fractures on February 3 and 4.

The first meeting will be under the direction of the Fracture Committee and will be held in the auditorium of the Hennepin County Medical Society at 8 p. m., February 3. At that time the subject of fractures in general will be discussed by representatives of the hospitals and the University of Minnesota.

On Thursday, February 4, Dr. Kellogg Speed of Chicago will be the guest of the Minneapolis Surgical Society. He will give a clinic with demonstration of cases at the Minneapolis General Hospital at 10 a. m. He will speak to the medical students at 2 p. m. in the Todd Amphitheater of the University Hospital.

The annual formal meeting and banquet of the Minneapolis Surgical Society will be held at the Nicollet Hotel, February 4, 6:30 p. m. Following the banquet Dr. Speed will deliver the annual address.

All these meetings are open to all members of the profession in good standing. Reservations for the banquet must be made with the secretary, Dr. H. O. McPheeters, Atlantic 5579, before 5 p. m., February 3.

Banquet tickets $2.00.

RICE COUNTY SOCIETY

The annual meeting of the Rice County Medical Society was held Wednesday, December 16, 1931, at 6:30 p. m., in the Main Hall at the State School for Feeble-Minded.

Dinner was served at 6:30 p. m. by Dr. and Mrs. J. M. Murdoch. The doctors' wives, local nurses and the Auxiliary were invited.

Following the dinner an entertainment was given by the children of the school. Addresses were made by Dr. J. M. Murdoch, president of the society; by Mrs. M. L. Mayland, president of the local auxiliary; and Dr. C. F. McClintic, Williamsburg, West Virginia, Professor of Neurology and Chief of the Department of Anatomy at the Detroit College of Medicine and Surgery, spoke on the subject of Headaches.

C. J. Plonske, *Secretary.*

RED RIVER VALLEY SOCIETY

The annual meeting of the Red River Valley Medical Society was held December 8, 1931, at the Hotel Crookston, Crookston, Minn. A banquet was served at 6:30 P. M. with guests, friends, and ladies of the auxiliary.

The scientific program consisted of the following:

1. "Presentation of Some Bone Lesions in Children."
   Lyle L. Brown, Crookston.
2. "The Management of Mastoiditis."
   J. G. Parsons, Crookston.
3. "Cancer of the Skin." Presented as a moving picture—courtesy of the Committee on Prevention of Cancer.

At the business meeting following the scientific session the following were elected as officers for the coming year: President, Dr. O. F. Mellbye, Thief River Falls; vice president, Dr. H. H. Hodgson, Crookston; secretary-treasurer, Dr. C. L. Oppegaard, Crookston; censor, Dr. H. H. Holte, Crookston; delegates, Dr. H. M. Blegen, Warren, and Dr. O. E. Locken, Crookston; alternates, Dr. O. J. Engstrand, Warren, and Dr J. F. Norman, Crooksotn.

C. L. Oppegaard, M.D.
Secretary-Treasurer.

SCOTT COUNTY SOCIETY

The December meeting of the Scott-Carver County Medical Society was held at the Broz Hotel at New Prague, December 8, 1931. H. M. Huenekens, Minneapolis, spoke on "Abdominal Pain in Infancy and Childhood"; Walter H. Ude, Minneapolis, on "The Diagnosis of Early Pneumonias with X-ray."

At the invitation of P. M. Fischer, Shakopee, it was decided to hold the next meeting of the society at Shakopee.

Boehler's technic in reducing fractures was discussed at the November meeting of the society, also held at the Broz hotel in New Prague. R. R. Cramer of Minneapolis spoke. A. C. Strachauer, Minneapolis, showed some interesting motion pictures taken in India in the course of a recent world tour.

WASHINGTON COUNTY SOCIETY

The meeting of the Washington County Medical Society, held November 10, 1931, at Stillwater, was of outstanding significance to the society, as we are about to launch on a new enterprise. We have for some time endeavored to align ourselves with the different activities devoted to the health of pre-school and school children, by giving examinations and tests, to give the protection to which a growing generation undoubtedly is entitled. From the start we have held this to be a very worth while insurance and therefore worth at least a nominal fee. We have and do insist on a fee, no matter of what size. We feel the medical profession has been and is continually asked to do altogether too much for charity. This Society has placed itself on record as willing, at all times, to render free service where it is actually needed, and without a murmur. However, this Society is also very anxious to act as a strong retention wall to help stem this tide of charity demand that is trying to engulf us from all sides. No other class or individuals are so persistently being made the target for charity seekers, societies or other combinations that would profit or be credited with, or able to further some project of their own by charity work done by the regular medical profession. We also believe that too much charity paves, or helps pave, the way for a very undesirable thing "STATE MEDICINE."

We have about completed arrangements for giving the Mantoux test to Junior and Senior students at our High School for a small fee. This will be our first step in the care tendered our school children as a society.

We have been slow in arriving so far, but we are slow so that we may avoid mistakes, and be able to profit by those made by others. We have sought, through our County Health Relations Committee and others, information from other sources helpful in this work. At this meeting Dr. Everett Geer, of Saint Paul, was specially invited to go over our plans with us, and Doctor Geer certainly gave us unstinted measure of his substance. As a result we now feel well prepared to go ahead with some benefit to ourselves and more so to those more chiefly concerned—the school children. In holding out for a fee for our work, we feel we are helping to fight a battle, the winning of which is of outstanding importance to every regular practitioner in the United States.

E. SYDNEY BOLEYN, M.D., *Secretary.*

WOMEN'S AUXILIARY

Minnesota State Medical Association

President—Mrs. James Blake, Hopkins
Chairman Press and Publicity—Mrs. Glen R. Matchan, Minneapolis
Editor—Mrs. Horatio B. Sweetser, Jr., Minneapolis

RICE COUNTY AUXILIARY

Dr. and Mrs. J. M. Murdoch entertained the Rice County Medical Society and the Medical Auxiliary at the annual dinner on the evening of December 16 at Faribault. Following the banquet an interesting program of music, dances, and a short play, was given by the children of the State School.

The meeting was then opened by Dr. J. M. Murdoch, president of the Rice County Medical Society.

Mrs. M. L. Mayland, president of the Auxiliary, told of the work the Auxiliary is doing, in the making over of clothing for the needy.

Dr. C. F. McClintic, of Williamsburg, W. Va., gave a very interesting talk on headaches.

The rooms were beautifully decorated with Christmas greens, and about one hundred guests were present.

STEARNS-BENTON MEDICAL AUXILIARY

Mrs. George Mosby was hostess to the Stearns-Benton Medical Auxiliary on December 4. At this meeting $10 was voted to the Minnesota Public Health Association.

WASHINGTON COUNTY AUXILIARY

On January 5, at a social meeting of the Washington County Auxiliary, it was voted that the money from the benefit bridge held in the Spring, with the addition of $9.00 already in the treasury, be used for installing a long needed drinking-fountain in the hospital.

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of November 11, 1931

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, November 11, 1931. After dinner at 7 o'clock, the meeting was called to order by the President, Dr. J. S. Gilfillan, at 8 o'clock.

There were 55 members and 2 guests present.

Minutes of the October meeting were read by the Secretary and approved as read.

Dr. William Davis read, for the Necrology Committee, the following memorial to Dr. H. J. O'Brien, and a motion was carried that this be placed in the permanent record of the Academy and a copy sent to the family of Dr. O'Brien.

DR. HENRY J. O'BRIEN
1862-1931

Joining the Academy in 1906, Dr. O'Brien was one of the older men both in membership and in age, as he was in his seventieth year at the time of his death, which occurred on September 16 last after an illness of only four days.

Born in the neighboring state of Wisconsin on April 21, 1862, he was brought to Minnesota in his early childhood and, after a general education in both parochial and public schools, he entered the Medical Department of the University of Pennsylvania, from which he received the degree of M.D. in 1888, beginning at once the practice of his profession.

Most of the limited surgery of that day was in the hands of a few general practitioners, one of whom, in St. Paul, was the late Dr. Everton J. Abbott, with whom Dr. O'Brien formed an early association. From the experience and instruction gained as Dr. Abbott's assistant, he soon developed an aptitude for surgery that in later years warranted his limiting his practice to that branch.

At this day it is not easy to realize the difficulties of those who fitted themselves to become experts in surgery at the time when the development of aseptic technic was adding in rapid succession one area of the body after another to the fields for legitimate surgical operation. These men had to learn everything for themselves for there was no one to teach them. Of this growth of surgery Dr. O'Brien was a part. He was recognized as belonging to the first rank of surgeons in the locality in which he practiced.

One of his most striking characteristics was his willingness to undertake some of the almost forlorn hopes of surgery. Where operation was the only chance, no matter how slender that chance might be, he was ready to give the patient the benefit of it, regardless of injury to his own surgical reputation by the probable failure. This was a part of a generous and unselfish nature which manifested itself in innumerable instances in his private as well as in his professional life. No deserving person who appealed to him for help of any kind was ever turned away.

Dr. O'Brien was a delightful companion. To a keen sense of humor and a ready wit was added the ability to describe any happening in a most entertaining way and to make the most of its interesting features. He will be missed sadly from our gatherings.

Your committee recommends that this memoir be included in the records of the Academy and that a copy of it be sent to Dr. O'Brien's family.

(Signed) E. M. Jones,
C. C. Chatterton,
Wm. Davis, Chairman.
The Committee.

The scientific program consisted of the following:

Dr. Emil S. Geist (Minneapolis) presented two patients on whom he had operated for Tuberculosis of the Tarsus. Dr. Petter, of Glen Lake Sanatorium, by invitation, showed X-ray lantern slides of these before and after operation.

About the middle of the last century Ollier performed and described a block resection of the tarsus in the case of tuberculosis of these bones. Several years ago I did this operation with good results and have since added two more cases, in my private practice, with three additional cases which we have done at Glen Lake Sanatorium.

The cases which I wish to present show perfect results with the type of operative treatment mentioned, while each patient has a different area of the tarsus involved.

Case 1.—E. H. This little girl presented involvement of the anterior part of the os calcis and posterior part of the cuboid, at the age of three years. Under routine sanatorium care plus fixation and heliotherapy for two years, the general condition improved but bone destruction occurred between the astragalus and scaphoid. Resection through the anterior portion of the os calcis and the astragalus, and through the cuneiforms and cuboid was performed on October 16, 1929. On January 9, 1930, a brace was applied, the child having been walking in a Böehler cast for about a month. She was discharged August 12, 1930. As you see, her foot is a bit shorter than the unaffected one. She walks well and has a good functioning member, two years following resection.

Case 2.—V. M., female, aged twenty-three. This patient presented a lameness and soreness over the dorsum of the right foot for one year before definite bone pathology was demonstrable. Finally an X-ray film revealed an infectious process between the scaphoid and cuneiforms which was thought to be tuberculous in nature. On April 8, 1930, an Ollier resection was done through the neck of the astragalus and calcaneocuboid joint proximally and through the cuneiforms and the cuboid-metatarsal articulation distally. The distal segment of the foot was drawn up and fastened to the os calcis and astragalus with heavy chromic gut. Six weeks postoperative a Böehler cast with stirrup was applied and the patient was allowed to walk. The brace was applied in October and the patient was discharged. As you can see, there is definite shortening of the foot but the function is good.

Case 3.—Mr. E. H., male, aged fifty-two. A typical Ollier resection was also done here. Healing occurred quite rapidly and the patient has now been ambulant for one year since the operation.

DISCUSSION

Dr. Arnold Schwyzer (St. Paul): It is a little over 30 years ago that a man came to my office with a foot that was at least twice the size of the normal one. He had tuberculosis of the tarsus. He was 18 years old at the time. We incised on the sides of the foot and scooped out the tarsal bones, leaving only a little of the shell of the bones. Of the astragalus, we removed the head and neck part, the cuboid scaphoid and cuneiform were scooped away, leaving only a partial shell. Iodoform was put in and the skin closed tight after the foot had been somewhat crushed together into a more normal form. There was fine primary healing. After about a year he came in again one day walking with crutches and with a foot swollen up as large as it had been before. I was utterly chagrined when the man came in in this bad shape. The patient, noticing this, said that the foot I had operated before was the one he was walking on now, and that the trouble was now in the other one. I operated upon this foot in the same way. Two or three years ago he brought his wife to our office for an operation and he told me he had never had any trouble with his feet for all these years.

These cases show how in tuberculosis of the foot, if the general condition allows it, you can get very gratifying results from conservative surgery in the young.

Dr. Moses Barron (Minneapolis) read his inaugural Thesis entitled "The Importance of Hepatomegaly and Splenomegaly in Differential Diagnosis." Lantern slide charts were shown.

DISCUSSION

Dr. S. Marx White (Minneapolis): This paper ought not to go without some discussion because with an enormous amount of work and detail Dr. Barron has taken a great deal of dead material and made it into a living study for physicians. I don't know of any other study like it. I think it is not necessary to comment on his conclusions. He has brought out and made clear the limited character of the material. In this climate and latitude many of the diseases causing hepatic and splenic disorders are rare, consequently are not present in representative amount. Within the limitations of the material, therefore, this analysis is useful to the clinician in the terminal stages of the disorders he has analyzed.

Dr. R. E. Scammon (Minneapolis): I wonder if, on behalf of those who are interested in the study of quantitative anatomy, I may express my appreciation of this paper. Those of us who are engaged in this kind of work have always felt the need of a study of this kind on borderline cases made by one with clinical experience.

Dr. Barron has spoken of the effect of blood content. So far as I know, the only work in this line was done a good many years ago by Sappy, who tied off the veins and arteries of the liver immediately after death and found that the liver weights thus obtained were about 200 grams above his controls, an increase of about one-seventh or one-eighth in the weight of the organ. So far as I know, no one has determined experimentally how much blood there is in the average spleen at autopsy. Dr. Barron's work indicates that the changes in spleen weight that may be produced by pressure of neoplasms on the splenic vessels are considerable.

I was very much impressed by the effect of subacute endocarditis on the weight of the spleen. For some years, in gathering supposedly normal spleen weights in children, we watched the records carefully for references to heart disease, and threw out all spleen cases with heart disease. Apparently, from Dr. Barron's work, we were justified in this procedure. It is interesting that Dr. Barron did not get any of these extreme splenic weights in gastroenteritis. I have always questioned the work of Stricker on this subject.

I was also very much interested in the weights Dr. Barron obtained in cases of accidental death. I wonder if we must revise our concepts of the normal weights of most viscera in much the same way as we have those of the thymus. Up to a few years ago we were describing hypertrophied thymi as occurring in cases of sudden death, and it was not until Hammar's work on cases of sudden death of known cause that we discovered our concepts of the weight of this organ were really based upon cases in which hunger atrophy had occurred.

Contributions of this kind will enable us to establish an adequate metric description of the human body.

Dr. C. B. Wright (Minneapolis): I want to congratulate Dr. Barron on this careful paper which bears out our impressions and conforms to the literature on this subject, namely, that malignant livers become very large before death and that leukemia is the common cause of large spleens. There are, however, many conditions such as cyst and cirrhosis which do produce large livers. Rolleston reports a cirrhotic liver that weighed 7,000 grams, in an alcoholic. The conditions that Dr. Barron describes are end-results of disease. From the clinical standpoint our greatest concern is in the *early* recognition of conditions of this kind. The difficulties in the early recognition of enlarging livers and spleens are many, such as thick abdominal walls, ascites, muscle rigidity, etc. However, this does not detract from the interest of the paper pathologically.

Dr. Barron (in closing): I wish to thank those of you who have so kindly discussed this paper. Dr. Scammon's remarks were especially interesting and they make me feel all the more the value of the study which I am now pursuing.

In regard to the question about the spleen in goiter, it is possible that one or two cases were encountered with large spleens but because of the rarity of the condition they may have been placed under the miscellaneous group. In the study now in progress there is a special group under goiter and this will probably bring out the variations in the size of the spleens. With reference to Dr. Wright's remarks, what I said in the beginning of my paper bears very pointedly on this subject. In the present study I have excluded all the questionable sizes and those that are just barely palpable. Most of the discussion centered on the definite hepatomegalies and splenomegalies where the livers weighed over 4,000 grams and the spleens over 600 grams. As you noticed, the organs that fell below these figures might be encountered under a large variety of conditions.

Dr. A. E. Wilcox (Minneapolis) reported three cases of Acute Abdomen Complicating Pregnancy, as follows:

Abdominal operative procedures during pregnancy generally are looked upon with great misgivings and considerable concern. However, there are certain definite emergencies complicating pregnancy which demand surgical intervention. Such surgical conditions may be classified as follows:

(a) The acute abdominal conditions.
(b) Pathological processes which later in pregnancy may interfere with labor, such as ovarian cysts.
(c) Pathological conditions which if allowed to progress awaiting delivery become unmanageable or threaten life, such as acute inflammatory processes.

The following three cases which are here reported come under the first class, namely, the acute abdomen. All were of extreme gravity and of a dramatic nature, requiring immediate operative treatment, and followed by as gratifying and successful results as could be expected in parallel cases occurring in the non-pregnant woman. When an "acute abdomen" develops during pregnancy a critical period is present. Loss of time in needless methods of investigation may be the deciding factor in mortality. I do not believe that too much stress should be laid upon the desirability of detailed diagnosis. The fact that an acute abdominal condition is present is sufficient. A tragedy has occurred which needs immediate and experienced attention. The general practitioner when confronted by such conditions need not feel humiliated by not carrying the diagnosis further. When surgical consultation and interference is sought, and this should be done as soon as possible, the combined conscientious effort should be to attempt to arrive at as correct a diagnosis as possible, yet under the most favorable conditions the acute abdomen will continue to remain only too frequently a mystery until the peritoneal cavity is explored.

Case 1.—Mrs. M., aged twenty-seven, seven and one-half months pregnant. About one month before admission, the patient had experienced some pain, rather severe in character, in the left lower quadrant of the abdomen. The pain was "shooting" in character and referred to the left shoulder. There was nausea, but no vomiting. Upon the day of admission she had been seized with severe pain in the lower mid-abdominal region, "cutting" in character, radiating to the left shoulder. Hypodermics of morphin failed to relieve the pain. Her doctor viewed her condition as one of acute abdomen. Upon admission to Eitel Hospital, January 30, 1930, her temperature was 98°, pulse 72, blood pressure 118/78, respiration 18, and leukocyte count 16,800. The abdomen was enlarged, compatible with a seven and one-half months' pregnancy, there was extreme tenderness on the left side, and marked rigidity elicited by palpation. Previous history and other physical examination was negative. A provisional diagnosis of acute abdomen was made, and while obstruction of the bowel was considered, no detailed definite diagnosis was ventured.

A left rectus incision was made. No free fluid was present in the abdomen. The uterus was smooth and enlarged nearly to term. There were two small fibroids on the posterior wall of the uterus. Adnexæ were normal. The omentum and mesentery of the bowel, small and large, as well as the epiploic appendages, showed white tubercles suggesting grossly either tuberculosis or fat necrosis. In the left epigastrium a mass about the size of a large lemon was felt which subsequently appeared to be the base of a volvulus or mesenteric thickening and the mesentery at this point was edematous. The first appearance of the small bowel was that of collapsed bowel, but on further evisceration the upper portions of the jejunum were dilated and cyanosed. This was followed down to the mass above mentioned and when the mesentery was untwisted, the color immediately returned in the bowel. No other pathology was found. The wound was closed with plain catgut, reinforced with chromic, interrupted and continuous in the fascia, silkworm close together and dermal for the skin. Post-operative diagnosis was volvulus of the jejunum complicating pregnancy.

Recovery was complicated by some nausea, inability to void, and the inevitable "gas pains." However, there was no alarming rise in temperature, or irregularity of pulse and respiration. Fifteen days after the operation the patient went into labor and was delivered by forceps without laceration. The child, a six-pound girl, lived and the mother made an uneventful recovery.

Case 2.—The following case presented an acute abdominal emergency immediately following labor.

Mrs. D., aged twenty-four, whose present complaints were abdominal distention, abdominal pain, weakness, vomiting, and inability to urinate. Labor pains began Friday, March 21, about 8 p. m. The pains were not severe. The membranes had ruptured two days before. The patient says she did not pass her urine Friday night after the pains began. About 11 p. m. Friday she complained of nausea and vomited, then went back to bed and was awakened at 2:30 by sharp pains. She thinks that at 3 a. m. the pains got much worse and she says she felt as though something broke. The doctor arrived at 3:30 a. m. The baby was delivered at 4:30 a. m., weight 7 pounds, normal, no instruments used. The placenta came normally, and there was normal flow. She says she had no pain after delivery. About 8 a. m. she started to vomit. She could not even retain water. There was no blood at first. The doctor came at 2 p. m. because of abdominal distention and continued bloody vomiting. She had not voided, but the bowels had moved. The doctor then catheterized the patient and 350 c.c. of bloody urine was obtained. The patient stated she noticed her heart pounding and distention of the abdomen was increasing rapidly.

Upon admission to the hospital the patient was slightly cyanosed, blood pressure 130/78, pulse 140, temperature 100.9°, respiration 28. Examination of the abdomen revealed fullness in the left lower lumbar region. It was difficult to make a fluid wave, there was no spasm or rigidity, and no vaginal bleeding. The patient was catheterized and 400 c.c. of dark brown reddish urine obtained and, upon pressure below the ribs and in the lumbar region, an additional 250 c.c. of the same colored urine was obtained per catheter. Microscopic examination showed blood cells and many crenated cells.

The presence of the blood in the urine obtained by a catheter, the abdominal distention, rapid pulse, and the expression of additional urine by pressure upon the abdomen suggested an injury in the genito-urinary tract and a tentative diagnosis of ruptured bladder was made.

The abdomen was opened and free bloody fluid escaped. The uterus was well contracted and free of adhesions. The bladder was drawn up and on its superior lateral surface a rent was found about two inches long. The bladder mucosa and walls were apparently normal. The bladder mucosa was repaired with plain catgut and reinforced with a layer of Dulox and several individual sutures to take off the strain. The wound was drained with two Penrose drains going down either side of the uterus. The wound was then closed with tier sutures and reinforced with silkworm. A mushroom retention catheter was inserted in the urethra. The pulse average was 167, fairly good quality, and irregular. Post-operative diagnosis was rupture of the urinary bladder.

Her convalescence, while somewhat stormy, was progressive, with complete recovery. On March 23 she developed severe herpes of the mouth, but otherwise made an uneventful recovery, leaving the hospital on the twentieth post-operative day. The patient has remained well to date.

Case 3.—Mrs. K., aged thirty-seven, mother of three normal children, and deliveries normal. She complained of pain in the abdomen, rapid enlargement of the abdomen, pregnancy, shortness of breath, and inability to lie down.

The patient thinks she is seven and one-half months pregnant and about two weeks ago she noticed very rapid increase in the size of the abdomen. During that time she had had some pain, but during the last night very severe pain started, especially on the right side. This radiated to the back and her abdomen became so tense and sore that she could not touch it, and she was unable to lie down because of the severe pain and dyspnea.

Upon admission her temperature was 98.6°, pulse 120, w.b.c. 10,000, urine negative, no nausea or vomiting, and her bowels moved normally. There had been no urinary disturbance in her past pregnancies. The abdomen was enormously enlarged, extended from the symphysis to the costal margin with almost board-like rigidity. On touching the abdomen lightly the patient complained of severe pain. Ballottement indicated fluid present, which was encysted and under great tension. No fetal heart tones were heard. The patient states that she thought she felt movements of the baby during the last two weeks, but not as active as before that time.

Irrespective of the pain the patient has had previously, the sudden onset of the pain before admission, and the enlargement of the abdomen suggested a rapidly growing ovarian cyst and, on account of the severe pain, probably a twisted pedicle. Ruptured uterus and acute hydramnios were also considered.

The patient was given a spinal injection of 200 milligrams of novocaine. A right rectus incision was made. When the peritoneum was exposed, there was a definite blue color beneath, which indicated blood present. In cutting through the peritoneum, the peritoneal cavity was filled with blood and clots. The peritoneum was very thick. All the blood was removed. The uterus was enormously enlarged, filling the entire abdominal cavity. Inasmuch as the source of bleeding could not be discovered, as the uterus was firmly fixed within the abdomen, it was decided with the consent of the family to do a cesarean section. The uterus was rapidly opened. Its walls were extremely thick and, when opened, clear hydramniotic fluid spurted forth, having been under great pressure. It is estimated that three gallons escaped. The child was rapidly delivered, but found to be dead, a monstrosity with anencephalus and spina bifida. The placenta was delivered intact and 1 c.c. of pituitrin was given directly into the uterus by hypodermic. I was then able to pull the uterus directly forward out of the abdomen and found a rupture on the right posterior area, below the attachment of the right tube. Some of the blood vessels in this area were the size of a little finger and bleeding was profuse. The walls of the uterus were closed with three layers of suture. There was another very weak spot on the left posterior surface of the uterus and this was sutured with chromic catgut. During these manipulations, the uterus relaxed considerably and 1 c.c. of ergot was given. Some additional large blood clots were found beneath the liver and these were removed and the abdomen closed without drainage.

Post-operative diagnoses: Hemoperitoneum, cesarean section, ruptured uterus, and monstrosity.

The pathological report of the monstrosity was anencephalia, craniorachischisis, meningomyelocele, pulmonary atelectasia, prematurity, absence of spinal cord.

This mother made the most uneventful recovery of the three cases. Her highest post-operative temperature was 102.2° on the fourth day. It rapidly returned to normal and continued within normal range. The patient left the hospital on the fourteenth post-operative day and has remained well without complaint to date.

DISCUSSION

Dr. A. C. Strachauer (Minneapolis): The diagnosis and treatment of the acute abdomen in pregnancy is the same as in the non-pregnant woman. The literature on the subject always emphasizes the importance of gentle manipulation at the time of operation. This is, of course, always important in the non-pregnant as well as in the pregnant patient. The most common acute condition of the abdomen complicating pregnancy is appendicitis. I personally have operated upon seven such cases. I recall two of these cases at the University Hospital, in which the appendix had ruptured, and in both cases the peritoneal infection was general. Dr. Litzenberg will recall them. Both of these recovered, as did the five cases without rupture, and without any miscarriages obtaining. We should have no hesitancy in operating upon any emergency surgical condition complicating pregnancy. Miscarriage is not likely and has not occurred in a single instance in my personal experience, which includes two cases of myomectomy, one of volvulus, and one of nephrectomy for an acute suppurative condition of the kidney. In conclusion, then, the pregnant woman should be treated the same as the non-pregnant, and miscarriage is a very unlikely occurrence.

Dr. A. T. Mann (Minneapolis): I think we all have had quite a number of cases of acute abdomen in pregnant women. It is quite remarkable how well they stand operations and how rarely they miscarry.

Of the many interesting cases there is one in which the uterus formed the anterior wall of a deep abscess. This was an acute appendicitis, and with an abscess outside of the appendix. The anterior wall was the uterus and the posterior wall the sacrum. The patient was six months pregnant. I opened the abdomen and left a drain in between the uterus and the sacrum. She had a normal child later at full term. Here was a case in which there was actual infection onto the wall of the uterus itself and nothing but a drainage tube between the uterus and the upper part of the sacrum.

Dr. J. C. Litzenberg (Minneapolis): These three cases presented by a general surgeon and discussed so far by general surgeons might give you the idea that any man will operate in these cases. But as an obstetric consultant, I have been surprised at the number of men who, because of the pregnancy, hesitate to open the abdomen in such acute conditions. Wherever there is an acute surgical condition or one dangerous to the patient, the pregnancy should be ignored. Usually the pregnancy is not interrupted by the operation. I think we may approach these cases with surgical judgment and without obstetrical fear.

Dr. Arnold Schwyzer (St. Paul): I think these three cases are unusual cases and very pretty ones. The first case where a simple free torsion of the mesentery caused obstruction is a very unusual one, though I have seen one such case. As Dr. Strachauer says, the most frequent cause of acute abdomen in pregnancy is probably appendicitis. I remember two cases of gangrenous appendix in pregnancy. Labor started and they both died. Thus I greatly fear the combination of pregnancy with acute appendicitis.

Dr. Wilcox's second case, rupture of the bladder in an otherwise normal labor case, is most unusual as it seems there had not yet been much labor pain, if I understood him rightly. I wonder if there was some peculiar weakness in the bladder wall. I have seen one case of rupture of the urinary bladder where 6,000 c.c. of urine were taken away from the bladder; but that was in a case of retroflexed pregnant uterus. That woman came to the hospital with peritonitis from perforation of the bladder due to distention ulcers. She died.

Dr. Wilcox's third case, rupture of the uterus, of course occurs, but here was a non-ruptured hydramnios and, if I understood the case correctly, there was apparently no severe labor pain.

I think, outside of acute appendicitis, the thing which is of comparatively most frequent occurrence is an ovarian tumor with twisted pedicle. When the uterus rapidly descends into the pelvis after delivery, the ovarian tumor follows and sometimes becomes rotated. I have seen this condition, and we have diagnosed it beforehand.

Dr. Wilcox (in closing): In Case 2, the history showed that this woman did not remember passing urine during the evening prior to delivery. She stated that about one and one-half hours before delivery her pain became very severe and she felt that "something broke," then the pain was much relieved. The probable and most plausible explanation of the injury to the bladder, in the absence of pathology therein, is that excessive pressure on a distended bladder during labor caused the laceration described.

Dr. F. F. Callahan (Pokegama) reported the following case of Tuberculosis of the Trachea, and showed specimen removed at autopsy.

Mrs. H. B., married, aged thirty-one, was admitted to Pokegama Sanatorium on August 31, 1931. Her occupation had been that of housewife for the past three years, and she had been a linotype operator for seven years previous to her marriage. She worked in an office with a boy who later developed tuberculosis and died. The family history is negative. She had measles and mumps in childhood, typhoid fever at 21 years of age, and tonsillectomy under local two years ago.

The first symptoms of her present illness were cough and loss of weight which began in the fall of 1929. She consulted a physician in the spring of 1930 who thought the cough was due to heart disease. A diagnosis of tuberculosis was made in April, 1930. She spent two months in bed in New Mexico, returning to Minnesota by car and has been in bed ever since. She has been short of breath for nearly a year and has had acute attacks of dyspnea since May, 1931. She developed bilateral cervical adenitis in the spring of 1931.

Physical examination showed evidence of parenchymal infiltration in the right side with a chronic pleurisy and probably a small effusion on the left side. The sputum was positive for tubercle bacilli. The blood examination was negative except for a low hemoglobin, 51 per cent (Sahli). The urine showed pus cells at two examinations. The Wassermann was negative at two examinations.

Her temperature ran from 100° to 102° most of the time; pulse 100 to 112. The patient always had difficulty in raising sputum and felt as if there was something in her trachea that she could not get out. A bronchoscopic examination was performed on September 17, 1931. This showed a shaggy exudate lining the entire trachea and extending into the main bronchi. Some of this exudate was removed and microscopic examination showed tubercle bacilli. The patient felt better for two weeks after the bronchoscopy and then began to have very severe attacks of coughing and dyspnea. She was considered too ill to be bronchoscoped again and on October 11 a tracheotomy was done by Dr. Gardiner. The patient died during the operation.

Permission was obtained for a partial postmortem, which was done after the body had been embalmed. The left pleural cavity was adherent over the base and there were many small adhesions over the remainder of the left lung. There were a few pleural adhesions on the right side. The heart and pericardial sac were negative. The abdominal cavity was negative There was a small ovarian cyst on the left side. The right lung showed many areas of caseo-fibrous tuberculosis. The left lung showed very few parenchymal tubercles. The lung was small and covered with a thick pleura. The entire trachea and large bronchi in the right lung were lined with an organized exudate. The tracheal rings seemed to be greatly weakened and the trachea was easily compressed. The exudate extended about 2 mm. past the bifurcation into the left main bronchus. The remainder of the left bronchial tree was negative. There were two slightly enlarged lymph nodes in the hilum.

The report on the microscopic sections of the trachea was tuberculosis involving the wall of the trachea including the cartilaginous rings.

The meeting adjourned.

R. T. La Vake, M.D., Secretary.

OVALTINE NOT ACCEPTABLE

The Committee on Foods reports that Ovaltine is a chocolate flavored dry malt extract, containing a small quantity of dried milk and egg which is sold with two slogans: "A food beverage" and "A food concentrate." From its examination of the product, the Committee concludes that Ovaltine is essentially a carbohydrate food, and that its value in gaining weight is no more nor less than that of other similar carbohydrate mixtures, and that Ovaltine is sold with grossly exaggerated claims; its composition is kept a mystery, and that even if it did contain what the manufacturer says it does, it could not do the things the manufacturer says it will. The Committee has listed Ovaltine with the products not acceptable. (Jour. A. M. A., December 12, 1931. p. 1798.)

PROCEEDINGS OF THE MINNEAPOLIS SURGICAL SOCIETY

Meeting of December 3, 1931

The regular monthly meeting of the Minneapolis Surgical Society was held in the lounge on the 20th floor of the Medical Arts Building, on Thursday evening, December 3, 1931, at 8 o'clock.

The meeting was called to order by the Vice-President, Dr. E. K. Green, in the absence of the President. There were twenty-five members and five visitors present.

The following scientific program was presented.

Dr. Verne S. Cabot reported "Two Unusual Cases of Carcinoma of the Colon." The patients were presented.

The two cases to be briefly described and shown here are of interest because of their age variance, the preoperative signs and symptoms, the favorable location of their tumor growths, as well as the choice of surgery employed.

Case 1.—The first case is a man forty years of age, an office worker, whose history shows nothing of importance until November, 1928, when he first began to notice abdominal distress, which was mild, cramp-like in character with maximum intensity in the right lower quadrant. These attacks were mild and infrequent in occurrence until April, 1929, when he had four distinct attacks, still mild in type, and unattended with gastroenteric disturbances sufficient to force him to call medical aid. The following month the attacks of abdominal distress became more persistent, associated with mild colic, most accentuated in the right lower quadrant and radiating to the epigastrium. The taking of food would often initiate the colic, at which time he would be somewhat nauseated, but there was no vomiting. He also noticed a tendency towards bowel looseness, even to watery stools, frequent in occurrence but small in amount. There was no history of melena.

He was first seen at this time, and while being subjected to gastro-intestinal examinations was seized by another similar attack, which sent him to the hospital with a tentative pre-operative diagnosis of acute appendicitis. There was no distention or evidence of reverse peristalsis. There was a slight leukocytosis. Beyond this, the blood and urine showed normal readings.

At operation, through a right paramedian incision an exploration of the abdomen revealed an annular mass at the junction of the middle and distal third of the transverse colon, to the left of the mid-colic vessels. The bowel at this point was not fixed, there were small glandular masses immediately adjacent to the tumor but none was visualized or palpated in the liver; only contiguous portions of the omentum were adherent. There was no distention of the proximal bowel. Approximately six inches of the transverse colon with the immediate gland-bearing portion of the mesentery and adjacent omentum were resected, followed by an end-to-end anastomosis, the suture line being brought up to the wound margin and covered by the remaining portion of the omentum, through which a Penrose drain was carried to the line of union.

His postoperative convalescence was quiet, the Penrose drain being removed on the fifth day. The sixth day there was a definite fecal discharge from the drainage tract left by the Penrose drain, which had been shortened daily and was out on the fifth day. The fistulous tract healed rapidly, being closed by the fifteenth postoperative day, and a week later he was discharged from the hospital. The removed segment of bowel showed an early annular carcinoma without marked ulceration or obstruction. He has worked continuously to date. Gastrointestinal studies as late as October, 1931, showed no narrowing or other abnormalities.

Case 2.—The second case is a woman past her 77th year, who, in December, 1928, first noticed increasing constipation which at that time was attributed to dietary factors and lack of exercise, partly due to advanced age and an arterial hypertension which averaged 200/100.

Her costiveness had gradually increased though enemata gave relief until May, 1929, when she was hospitalized for her increasing obstipation. For two weeks prior to her entry to the hospital she had complained of spasmodic cramp-like pain located at and below the umbilicus, intensified after meals and relieved by colon flushings. Gastrointestinal examinations revealed a partial obstruction in the lower portion of the descending colon and a tentative diagnosis was made of carcinoma with partial obstruction. There had been no history of melena or hematemesis. There were no demonstrable metastases.

This elderly lady was wholly in possession of her mental faculties and when advised of the findings at first refused to consider a colostomy. However, through a left paramedian incision an exploration of the abdomen revealed a small carcinomatous growth annuluar in type involving the lower descending colon at its juncture to the upper sigmoid. There were no visible or palpable metastases. There was no abnormal fixation of the mass. Glands immediately adjacent to the bowel at the tumor site were enlarged. There was no marked distention of the proximal colon.

In view of her age, general condition and the operative findings, a one-stage procedure was adopted, in which the carcinomatous area with adjacent glands with a portion of mesocolon was resected. An end-to-end anastomosis was done, the union being brought up to the wound margin and partially walled off by omentum. A single Penrose drain was placed at the line of suture. Her post-operative convalescence was entirely uneventful. There was no subsequent vomiting or rectal bleeding. The drain was out by the fifth postoperative day. The healing of the wound was by first intention. She was discharged from the hospital on the 18th day following her operation. The resected portion of colon showed a small circular carcinoma with only moderate narrowing. There was but little evidence of ulceration. To date there has been no further complaint referable to the gastrointestinal tract. Subsequent X-ray studies, the last of which was in October, 1931, show only a slight narrowing at the site of resection.

These cases are interesting because of the early date of their recognition and resection, especially so since most often severe and prolonged obstruction with its concomitant sequelæ precedes surgical intervention. The indications for a one-stage procedure, with or without proximal decompression, seldom present; however, in those cases seen early where the tumor is favorably located and in which obstruction is not the predominant factor, it may be of value in selected cases.

DSCUSSION

Dr. F. A. Olson said he would like to ask Dr. Cabot how he did this end-to-end anastomosis?

Dr. Cabot replied that one was done with cautery and the other with the knife.

Dr. E. A. Regnier asked which one had the fistula.

Dr. Cabot replied that the one done with cautery had the fistula. One would think it would be just the other way, but not in this case.

Dr. Regnier thought that the great part of Dr. Cabot's cases was the fact that he was able to do one-stage resections without complications. He stated that there were arguments for and against one-stage procedures: (a) frequently the size of the tumor; (b) amount of inflammation about it; (c) the degree of infection and varying degrees of obstruction make a two-stage procedure more favorable. He asked Dr. Cabot whether in his opinion this type of resection gave his patients as good a prognosis as is possible by a two-tage procedure.

Dr. Cabot replied that this is a debatable question. The one-stage of course has to be in the non-obstructive type. There are less lymphatics in these two areas. Neither of these patients was infected, they were practically non-obstructive and there was no fixation. As far as elevating the mortality risk, he was of the opinion that the one-stage procedure did not do so in either of these cases. The woman was well along in years and had a high blood pressure, and to submit her to two operative procedures he felt would be more of a risk than one operation. Both of these patients lent themselves very well to the one-stage operation. Possibly in the case of the man the risk might have been increased a little by doing the one-stage operation. Dr. Cabot felt that all in all it was preferable in these two cases. Certainly the hospitalization time was shorter, but of course he realized that is not the primary consideration. He mentioned that according to the literature they are doing the one-stage operation in England more and more. And in suitable cases he felt it was a good thing.

Dr. Regnier asked how wide a resection was done.

Dr. Cabot replied about six inches.

Dr. Regnier asked if the same amount of mesentery was used.

Dr. Cabot stated that it was cut down to a V. In the grandmother there was a question of malignancy in a gland of the adjacent mesocolon, but in the man there was none.

Dr. E. A. Regnier reported a case of "Carcinoma of a Tranverse Colon with Secondary Perforation into the Ileum."

The patient, white, female, aged twenty-four, was admitted to the Minneapolis General Hospital on June 26, 1931.

She complained of bloody diarrhea of two weeks' duration; abdominal cramps and nausea of two weeks' duration; and gradual enlargement of an abdominal mass of four months' duration.

Four months previous to the present admission to the hospital, the patient had been delivered of a normal female child at Minneapolis General Hospital. There were no obstetrical complications. Shortly after returning home following the delivery the patient had noticed a small mass to the right of the umbilicus. This mass had grown slightly during the past four months, was freely movable and not tender. Two weeks previous to admission she noticed the beginning of a severe diarrhea. Bowel movements were accompanied by severe abdominal cramps. There was nausea but no vomiting. Four days previous to admission she noticed dark red blood in the stools, and she became very weak. She states that she felt feverish. She had lost about twenty pounds in weight.

The past history and family history were entirely negative. She was married at nineteen years of age. Her husband is living and well. She had had three pregnancies, all normal.

The patient was a well-developed but poorly-nourished, young white woman, and appeared very languid and very pale. The physical examination was entirely negative except for the abdominal findings and the pallor of the mucous membranes. Her blood pressure was 110/80. There was a slight tenderness throughout the abdomen. There was a mass the size of a man's first, firm, freely movable, moderately tender, just to the right of and slightly below the umbilicus.

The Wassermann test was negative. The urine was negative. Her hemoglobin was 42 per cent, r.b.c. 3,000,000, w.b.c. 7,000, p.m.n. 57 per cent, lymphos. 43 per cent. Temperature 100°. The stools were negative for amebæ and parasites, but showed 4 plus blood. The barium studies showed obstruction in the mid-transverse colon with two enterocolic fistulas at the site of obstruction. (A series of X-ray plates were shown.)

The diagnosis was probable malignancy of the transverse colon with perforations into the ileum.

The patient was given a blood transfusion, subcutaneous fluids and high carbohydrate diet of low residue, and on the 14th day of July, 1931, subjected to operation under ether anesthesia. Carcinoma of the transverse colon with two perforations into two separate loops of the ileum was found. The entire mass was adherent to the stomach wall. There were mesenteric nodes which were enlarged. A double loop of ileum was resected about 18 inches in length and end-to-end anastomosis was done to reconstruct the ileum. The mass was freed from the stomach by resecting about three inches of the outer coats of the stomach in the distal portion of the greater curvature. The entire mass was then brought out of the abdomen as in the classical Mikulicz procedure. The patient was transfused following the operation. Forty-eight hours later the tumor mass was resected by cautery, removing about nine inches of transverse colon. A Mikulicz clamp was then inserted in two loops of colon to reestablish the continuity of the bowel. The patient was discharged from the hospital on the 8th day of August.

At the time of this writing the patient is entirely well, has gained 25 pounds in weight, and the wound is entirely healed. Her hemoglobin is 75 per cent.

The pathological report on the tumor was adenocarcinoma of the transverse colon.

Dr. Regnier stated that his purpose in bringing this case to the attention of the Society was to stress the advisability of doing radical surgery in these apparently hopeless cases when there is at least an even chance of prolonging life in comfort. Obviously this seemed like a very radical procedure in the face of great odds, but it was also obvious that this patient could not have lived a month longer without surgical interference. He believed that a two-stage operation was the method of choice in this case. He felt that the ultimate prognosis was not good but the patient has been so well since the operation that he thought the procedure was entirely justified. He believed a great many cases of carcinoma which seem inoperable at the outset can be greatly benefited and in some cases cured by this method of treatment, especially when it is the only means at hand of offering a patient any relief whatever.

DISCUSSION

Dr. F. A. Olson asked Dr. Regnier and Dr. Cabot if they had used the inoculations as recommended by Dr. Bargen.

Dr. Regnier replied he had not used any inoculations. There had been a great deal of difficulty in isolating organisms and there was no conclusive proof that these inoculations were specific. He stated that his own case had been thoroughly vaccinated during the previous three months through the two perforations between the colon and the ileum.

Dr. H. O. McPheeters briefly discussed the injection treatment of varicose veins with special reference to some special work he had done along that line. He stated this particular work was undertaken with three points in mind: (1) to prove the moot question of the reverse flow of blood in varicose veins; (2) that the best results obtained in the treatment of varicose veins are obtained by utilizing the value of this reverse flow; and (3) that many recurrences following the injection treatment are not real recurrences but only incompletely treated cases.

He based this work on the assumption that the direction of flow of blood in the varicose veins could be accurately determined by the blood pressure readings taken at different points along the vein. With that idea in mind, coincident readings were taken with manometers attached to 12-gauge veterinary needles inserted into varicosed loops along the vein. One needle was inserted in the calf, one internal to the knee, one in the mid-thigh, and one into the deep femoral vein just under Poupart's ligament. The readings were then taken with the patient lying prone and erect. The change of posture was brought about by having the patient on a tilting X-ray table.

The results of the blood pressure readings clearly showed that the direction of flow in a fully-developed case of varicose veins was from the sapheno-femoral opening downward to the calf. This work will be reported in full in an early issue of Surgery, Gynecology and Obstetrics.

Dr. McPheeters then showed several slides of varicose veins that had been injected with skiodan. These showed the ramifications of the veins and the connection with the deep system. It also visually confirmed the reverse flow as proven by the blood pressure work. The skiodan slides further proved that the injected solution could be localized almost perfectly by means of the tourniquets and the posture of the injected limb.

DISCUSSION

Dr. Regnier asked if he understood Dr. McPheeters to say that one needle was put directly into the deep femoral vein.

Dr. McPheeters replied that he was exactly right. He said that for about one inch below Poupart's ligament the femoral vein lies internal to the femoral artery and that in this area the needle could be accurately introduced directly into the femoral vein. He also stated that the blood pressure readings had been taken in eight cases thus far.

Dr. Daniel A. MacDonald read his inaugural thesis entitled "Double Uterus and Vagina with Unilateral Atresia." (Paper to be published in full in Minnesota Medicine.)

ABSTRACT

The paper gives a brief résumé of the surgical problem of congenital malformations of the uterus and vagina. Under embryology, the union of the two Müllerian ducts, the formation of the wall of the uterovaginal canal and the development of the musculature of the uterus are reviewed.

The classification of double uterus includes uterus bicornis bicollis, uterus bicornis unicollis, uterus septus, uterus subseptus, and uterus didelphys.

The obstetric complications of double uterus considered are: dystocia, rupture of the mesial wall of the uterus, and postpartum hemorrhage.

Due to the wide variation of conditions met with, each case is a law unto itself and no set rules can be formulated as to treatment. Mention is made of utriculoplasty, unilateral hysterectomy, simple sterilization, and bilateral hysterectomy, as indicated in certain cases.

Dr. MacDonald reported a case of uterus didelphys and double vagina with unilateral hematocolpos and hematometra.

DISCUSSION

Dr. Jalmar Simons of Minneapolis had been invited to open the discussion of Dr. MacDonald's thesis.

Dr. Simons said he appreciated very much the invitation to discuss Dr. MacDonald's paper, which was very interestingly and ably presented. The slides he has shown give an idea of the great number of defects that can result from improper fusion of the Müllerian ducts and the wonder is that here, and elsewhere in the human body where fusion is a vital embryological phenomenon, so few defects occur. Thirty-seven types of genital deformities have been described; the uterine deformities, in order of their frequency, are: (1) uterus bicornis, (2) bicornis unicollis (single cervix), (3) uterus didelphys; the vagina showing frequently partial or complete septums, unilateral or complete atresias. The incidence, according to the most reliable statistics, is one defect in 1,500 gynecologic cases. The records at the Minneapolis General Hospital show one in approximately 1,200 cases as follows: uterus didelphys discovered during an operation for appendicitis; bicornate uterus during an operation for ovarian cyst; complete absence of uterus in a tuberculous patient, there being only a plaque of tissue where the uterus ought to be; two cases of pregnancy in a rudimentary horn, both diagnosed as ectopic.

Vaginal and cervical malformations are diagnosed with ease, but uterine deformities, in the absence of vaginal and cervical malformations as a lead, are often misdiagnosed as uterine tumor and pelvic cysts, and the rudimentary horn pregnancy as ectopic. As shown by one of Dr. MacDonald's slides, the latter may be quite advanced principally because syncytial erosion sufficient to produce significant symptoms of intraperitoneal hemorrhage does not occur until the pregnancy is farther advanced than in ectopic. The mass itself is apt to be considerably larger than an ectopic, and one should be suspicious if vaginal or cervical deformities are present and if contractions occur in the mass.

Deformed uteri are prone to adnexal inflammation and to cause hematocolpos, hematometria and hematosalpinx if there is vaginal atresia, as in Dr. MacDonald's case.

Pregnancy occurs in the presence of genital malformations, according to some reports, about once in 1,500 consecutive cases. There is no depreciation in fertility; abortion is much more frequent; malpositions are more common; accidents of labor are likely, such as abruptio placentæ, retained placenta, rupture of the uterus, and postpartum hemorrhage. Operative deliveries are five times more frequent; morbidity eight times and mortality for the mother four times as great, with a fetal mortality five times the nomal. Here, then, pregnancy is a foreboding condition.

Dr. MacDonald's case of uterus didelphys with double vagina and unilateral atresia was sure to develop symptoms as soon as she began to menstruate and increasingly ominous symptoms which each menstruation. Her symptoms were typical but the physical signs were not adequate for a definite diagnosis before operation.

Dr. Simons felt that the treatment of Dr. MacDonald's case was admirable and he thought the doctor showed considerable ingenuity in treating the blind vaginal pouch as he had. Having excised the uterus with as much of the atresic vagina as possible, he packed the remainder with gauze with the idea that this would produce an adhesive inflammation and, when pulled out through an incision below, the pouch would soon obliterate itself, leaving, as he stated, a small depression to the left of the normal vagina. The opposite uterus was smaller and attached to the right pelvic wall by a very short broad ligament. Pregnancy in this uterus would become a serious affair, so he chose to remove it. Tubal ligation might have been done, leaving the menstrual function for psychic effect. Her amenorrhea, if properly explained, would most likely be accepted with the feeling of a burden eliminated.

Dr. Willard Peterson said he would like to ask a hypothetical question. If a girl should come to her doctor for an abdominal condition such as appendicitis and at operation one of these uterine abnormalities was found, what would the surgeon be justified in doing?

Dr. Otto Yoerg stated that this was a very interesting paper. It reminded him of a case he had seen in his internship days, of a woman who came in to be delivered. The physician was not aware of the fact that the woman had a double uterus. One vagina was about normal in size and the other admitted a finger. Delivery and convalescence were normal.

Dr. Regnier asked about removing the blood cyst from above without opening from below.

Dr. MacDonald stated that the idea of opening below was for drainage and to remove the gauze.

He also added that the literature for the most part deals with the obstetric complications. He recalled one case reported where a diagnosis of ectopic was made and upon opening the abdomen it was found to be a pregnancy in the right horn of a bicornate uterus. The appendix was removed and the abdomen closed. The patient aborted nine days later. She later became pregnant and was brought in at term bleeding. X-ray showed the fetal head in one horn and buttocks in the other. A low flap cesarean section was done. The patient had a stormy course and one week postoperative had a very severe postpartum hemorrhage. Transfusion saved her life but the gynecologist felt that after such a harrowing experience and reading the reports of others, he questioned if one was justified in leaving in the pelvis such a malformed uterus to endanger the woman's life with a future pregnancy. Still another man, who advocates conservatism, had removed the right tube and horn of a bicornate uterus. The patient became pregnant and was brought in near term in a moribund condition. A postmortem was not obtained. Under the circumstances the doctor regretted that he had not removed the left tube also at the time of operation.

In cases of uterus didelphys the right uterus is usually the lesser developed, as is also the right horn of a bicornate uterus.

As far as the frequency of malformations of the genital tract is concerned, Dr. MacDonald stated that, excluding minor defects, Von Winkel in 600 autopsies on females found 2 per cent to have malformations of the sexual organs. Norman F. Miller of Ann Arbor (Amer. Jour. Obs. & Gyn., 1922) collected 54 cases of true uterus didelphys from the literature in addition to one case from the University of Michigan. In the 54 cases there were 34 married women, 31 of whom became pregnant (91.1 per cent). One of the single women became pregnant also and in all there were 67 pregnancies for the 32 women. Normal birth at term occurred in 28 of the 67 pregnancies (41.7 per cent) though a great many of these labors were undoubtedly prolonged and tedious; 19 of the 67 aborted in the early months (28.3 per cent). He also cites Bayard as reporting 14 abortions in 14 cases (100 per cent).

While abortions in general occur in 24 per cent of pregnancies, Miller calls attention to the fact that 32 per cent of abortions are self-induced, and in not one of the cases in the 32 women with uterus didelphys was there a history of self-induced abortion. Forty per cent had complicated labors at term. The most frequent complication in the abnormal deliveries at term was due to the enlarged non-gravid uterus obstructing (23 per cent). Dr. MacDonald stated that the non-gravid uterus enlarges with the gravid uterus during pregnancy to about the size of a small grapefruit.

In the 67 pregnancies reported by Miller, manual removal of the placenta was necessary in 8 (11.9 per cent). In the 54 cases, 42 were associated with double vagina.

Dr. S. H. Baxter asked about sterilizing the patient and leaving the rest of the surgical procedures.

Dr. MacDonald replied that he would consider simple sterilization the ideal treatment in a great many cases. In his own case, however, the round ligament was so short that the right uterus would be lying next to the pelvic wall with a danger of torsion. He also felt that the right vagina should be supported medially in the pelvis. This girl had a pelvis 1 to 2 cm. wider than the adult female pelvis. This, with short round ligaments, was a probable factor as far as the cause of the malformation.

If one is going to treat these cases conservatively, and feels that hematosalpinx does not exist, an incision (wide) in the intervaginal septum can be made. Do not irrigate or introduce any drainage material. Do not make a bimanual examination. Place the patient in Fowler's position and watch carefully for the first symptoms of peritoneal infection. If they occur, immediate laparotomy will probably reveal a ruptured tube. The retention cases reported by Miller were diagnosed on an average of two and one-half years after the beginning of menstruation. The danger of dilatation of the upper genital tract must be remembered.

Dr. Simons said that the incidence of flat pelvis in these cases further complicates the pregnant state. He reported a case of a girl 13 years of age who came to the hospital with very acute pain in the lower abdomen and a history of two similar attacks of less severity. There was no vagina but she had a hematometra of the size of a 3-months' pregnancy. At the introitus a line of cleavage was found which dissected up to this mass; the mass was then punctured, liberating first tarry, then brown, then red blood. A tube was sewed in for drainage and to establish a permanent canal. Two years later, examination showed a somewhat atresic vagina, and a history of normal menstruations was obtained.

Dr. MacDonald said that in 32 cases of retention reported by Wells (Amer. J. Obst., 1900) there were 11 deaths. Of these 11 deaths, 9 occurred from septic peritonitis after puncture of the sac from below. He added that though the mortality undoubtedly is much lower today with the same procedure, there are recorded deaths even where laparotomy has been performed with the first symptoms of peritoneal infection.

There was no special business to come before the Society at this meeting, and upon motion the meeting adjourned.

H. O. McPheeters, M.D., *Secretary.*

OYSTERS—A PLEASANT TYPE OF THERAPY

The announcement three years ago that copper is effective in supplementing iron in the cure of anemia produced by an exclusive milk diet in the rat promptly aroused interest. The inferences drawn by others than the investigators themselves has led to confusion and mistaken advice. There has been no warrant whatever in applying the observations without reservation to some of the unusual conditions of the blood, such as pernicious anemia in man. At the moment there is some debate whether copper stands alone in the capacity to promote the function of the iron in hemoglobin and blood cell formation. Other elements, such as manganese and germanium, are clamoring for equal recognition. Meanwhile all sorts of new products containing both iron and copper are foisted not only on the ignorant public but also on an uncertain medical profession. The chief objection to such unproved therapy is the sense of false security which leads to the neglect of other modes of therapy that may be far more effective. Recent investigations have shown oysters to be capable of curing the nutritional anemia of milk-fed rats. The studies indicate that the inorganic elements present in the oyster are responsible for its hemoglobin regenerating capacity and that the antianemic potency of the oyster can be accounted for on the basis of its content of the three elements iron, copper and manganese. (Jour. A. M. A., December 26, 1931, p. 1970.)

Berkeley George Andrew Moynihan, Baron Moynihan of Leeds, president of the Royal College of Surgeons, had a look at Sculptor Jacob Epstein's Genesis, grotesque figure of primitive pregnancy. Wrote he to his newspaper: "I regret to say that, in my opinion, Epstein is almost certainly guilty of an error in diagnosis. The lady, I think, is not pregnant. . . . The abdominal tumor in position and in salience is not that of pregnancy. . . . The mammary condition is that of an adipose virgin and not of a primiparous woman whose delivery is drawing near. . . . On the available evidence . . . I believe that the hopes of her admirers will be disappointed, and that no new birth is about to reward her for her obvious suffering. I can almost fancy that her expression indicates that she herself is beginning to realize this."—*Time,* Dec. 14, 1931.

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

MEDICINE

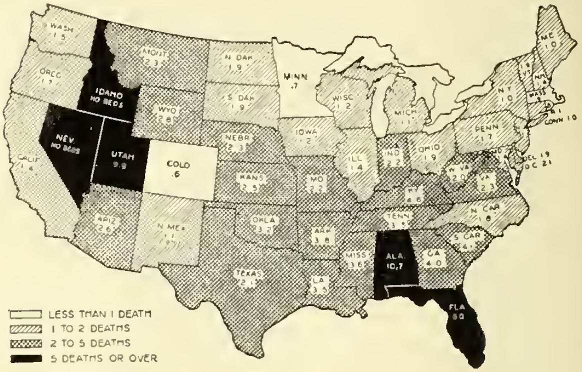
TUBERCULOSIS ABSTRACTS*

It is estimated that there are in the United States about 828,000 cases of active pulmonary tuberculosis. The total number of hospital and sanatorium beds now occupied by tuberculosis patients is about 80,000, leaving a remainder of 748,000 patients who are either receiving treatment at home or none at all. Perhaps most of those who take the cure at home do so because they are not persuaded of the advantages of the sanatorium. Others cannot enter institutions even though they would, because of inadequate local provisions. A considerable number pursue the cure at home on the advice or at least with the tacit consent of the physician. Paul H. Ringer at the eighty-second annual session of the American Medical Association discussed the question of home treatment versus institutional treatment of pulmonary tuberculosis. Abstracts of his paper follow.



Number of beds for tuberculosis cases compared with number of deaths from tuberculosis—1928. (Exclusive of federal and penal institutions and hospitals for the insane.)

HOME TREATMENT VERSUS INSTITUTIONAL TREATMENT

The uniform success achieved by sanatoria in all parts of the country has led to the belief that climate counts for nothing and that, therefore, the cure may be carried out just as well at home. But this attitude overlooks the prime object of the institution; namely, the education of the patient. Moreover, in the sanatorium, rest is found for the mind as well as the body, for there are no responsibilities and a patient is surrounded by a sympathetic environment.

In only a minority of cases will home treatment work. Taking the cure is like finding "a way of life" and that way is particularly hard for the patient to follow at home. If there is nothing more to the treatment than bed rest, reasons the patient, he might better be at home. If he has a good home, that might be true but the point he overlooks is that, in addition to bed rest, there are details one learns from physicians, nurses, and other patients, the force of example, and the common routine. A period of quiet and of relative isolation helps the patient to regain his composure, after having been upset by the news that he has tuberculosis. He makes his adjustment to the necessary and tedious inactivity in the company of others who are trekking along the same trail.

In an institution, the regimen is so planned as to make it easy to do the right thing. The patient must deliberately step out of line in order to do the wrong thing. At home, the patient is forced to swim against the tide, for relatives and friends have scant realization of the limitations that must be placed on the patient.

The patient at home may obtain bodily rest, but relaxation, that is, freedom from mental strain, is difficult to secure. He is subject to disturbance by (1) the family, (2) friends, and (3) business. Family irrita-

tion, not rare in health, is aggravated in time of sickness. Overanxiety of relatives, a deleterious influence even in an illness of short duration, becomes a factor of major seriousness when exerted over a period of many months. The normal chatter and noise of young children render the patient's nervous system taut. At the same time, the desire for expressed affection leads to many contacts and repeated exposure of the child to tubercle bacilli. All of the minor ailments and petty misunderstandings of the household impinge themselves on the consciousness of the patient, even in an affluent home, and more so in one of poor circumstances.

The control of visiting friends is almost impossible. Strict visiting hours cannot be maintained. If there is a nurse, she is likely to be off duty during several hours in the afternoon, which is the time when friends commonly call. The disturbing gossip retailed by visitors who stay on and on leaves the patient fretful or worn out. Unsolicited advice about food and rest and "harmless" diversions, such as going to the movies or taking an auto ride, undermine the patient's morale.

Business associates are a disturbing element. Matters come up which by discussion in person or over the phone "take only a minute" to settle but leave hours of disquiet and worry. Business friends drop in when it is convenient to them and talk shop, which leaves the sick man unsettled in his mind and rebellious at the fact that he cannot take an active part. These difficulties, in principle, apply with equal force to women patients.

Most patients do best at an institution some distance away from home, say 200 miles. Visits of relatives are more difficult and telephone conversations less frequent. A factor to be considered is the enthusiasm, anticipation, or hope engendered by going away to a favorable environment; this the patient cannot possibly have if he simply goes to bed amid familiar surroundings.

THE DOCTOR SHOWS THE WAY

The determination to get well is essential. We physicians can only point out to the patient "the way of life"; mark the highway, warn against side roads, steer clear of impassable byways. We cannot carry the patient one yard, save in those cases in which lung surgery can be employed.

The author does not advocate sending the patient away from home immediately subsequent to a diagnosis of tuberculosis. Patients with tuberculous bronchopneumonia and patients who have had hemoptysis with subsequent areas of softening, accompanied by high fever and evidences of acute illness, are much better kept at home until the initial acuteness of the condition has subsided and they can be moved with relative safety. Nor should patients be "railroaded" out of their homes without being given time to take in the situation or to adjust themselves to what appears to be a cataclysmic upheaval in their lives.

The author feels that the great benefits to be obtained from leaving home and preferably from institutional treatment are as much psychic as physical; but in the case of tuberculosis, the psychic and the physical are so intimately blended that it is next to impossible to evaluate one above the other.

DISCUSSION

Dr. James Alexander Miller: The proper regulation of rest and exercise by which each patient gradually learns his individual limitations is the most essential element in the system of cure. As with many other forms of education, this knowledge comes only by long, persistent effort. Schools are more effective than home study or correspondence courses. A sanatorium is a school for health. The patient learns unconsciously from the example and experience of his associates. He need not learn entirely from his own mistakes, which are often costly. Gradually, the knowledge of his limitations leads him to a habit of life which is instinctive and consequently no longer irksome. The skilled guidance of a trained physician, experienced in the care of chronic diseases, thoughtful of varying temperaments, capable of giving inspirational guidance, always patient and persistent, helps the patient to acquire not only a habit but a philosophy of life which enriches his life.

Dr. A. M. Forster: I was interested in what Dr. Ringer said about the difficulties of home treatment as compared in men and in women. I use an illustration in talking to the woman who wants to go back to her children. I tell her that if we took her husband and put him in his office on a cot and told him that all he needed was rest, and that he need pay no attention to the bookkeeper or to the customers or to his partners or to the telephone, and would simply get himself into the proper psychologic state and would rest, then that situation would be comparable to what the woman has to submit to when she attempts to take a rest cure in her own home.

Dr. James M. Anders: Treatment in a sanatorium some distance from home is more nearly ideal, although to remove the patient a long distance has certain disadvantages. The force of example as an aid to the patient has been under-estimated. In general, a stay of from nine months to a year is required to teach the patient the institutional regimen. When he has mastered that and if he possesses average intelligence, the treatment may continue at home.—*Pulmonary Tuberculosis—Home Treatment versus Institutional Treatment, Paul H. Ringer, Jour. of the A. M. A., August 8, 1931.*

A STUDY OF THE FIVE-HOUR DEXTROSE TOLERANCE CURVE IN TREATED DIABETIC PATIENTS: Elaine P. Ralli, M.D., and James Shannon, M.D. (Amer. Jour. of Med. Sci., September, 1931). This is a study of the effects of the glucose tolerance test on a number of treated cases. The cases were first classified clinically as mild, moderately severe, and severe, and then the results from the glucose tolerance test were compared with the classifications previously made. In general, they coincided.

There has been some obscurity in interpreting the normal glucose tolerance test. In normal cases the greatest elevation of the hyperglycemia is from one-half to one hour after the ingestion of glucose. The blood sugar returned to normal in from two to three hours. In the mild cases the greatest elevation of hyperglycemia occurred from one to two hours after meals, and dropped back to normal in from three to four hours. In the moderately severe the hyperglycemia was variable, and the return to normal was at the end of a four or five-hour period. In the severe cases there was marked hyperglycemia during the whole five hours.

This short paper is of value in a practical way because it shows that a five-hour glucose tolerance test gives more information than the usual three-hour test.

The important conclusions derived from this study are as follows:

1. There is evidence that in a starving blood sugar of over 0.16 mg. the patient will not return to the normal blood sugar in five hours; in other words, it indicates a severe diabetes.

2. The blood sugar taken four hours after meals is a far better index of severity than the starving blood sugar. In general, a five-hour determination will give more information than the usual three-hour test. The duration of hyperglycemia, rather than the elevation. is of more clinical value.

Richard Bardon, M.D.

CARBOHYDRATE METABOLISM IN RELATION TO POSTOPERATIVE CRISES IN HYPERTHYROIDISM: Charles H. Frazier, M.D., Sc.D. (Amer. Jour. of Med. Sci., Sept., 1931). The conclusions from this article are also of considerable practical value.

In exophthalmic goiter there is a decrease in the islands of Langerhans. This was reported in 1921 by Holst. Hyperthyroidism exhausts the glycogen store in the liver, and according to the author the liver seems to be the only source of blood sugar.

The rational treatment of crises following hyperthyroidism has to do with the use of intravenous glucose. A crisis may demand sugar over and above the available supply, and may precipitate a fatal hypoglycemia.

For some years glucose has been used in the postoperative treatment, but not very intelligently. Frequently it is given by rectum—a method now known to be totally ineffectual. It can be given by mouth, except that one cannot control the rate of absorption. When given intravenously, numerous precautions are necessary. It has been found out by Wilder, in 1917, that the normal individual can take care of .800 gm. of glucose per kilogram of body weight per hour when given intravenously, but the patient with hyperthyroidism develops glycosuria when as much as 0.6 gm. of glucose per kilogram of body weight per hour is injected. This would indicate faulty glucose assimilation.

The author recommends the administration of glucose solution but believes that it should not be given too rapidly or in too high a concentration. Usually a 5 to 10 per cent solution is the most satisfactory concentration, and the slow intravenous, continuous drop, has many advantages over the other methods, as it permits the addition of fluid at a rate at which the tissues, which normally take a part in the storage of water, can accommodate it. Just what causes these postoperative crises is, as yet, a matter of speculation. The author believes that glucose helps to tide the patient over a very critical period, and suggests that possibly the entire process is one of a disturbed carbohydrate metabolism, where the problem may be even more complicated.

There is considerable evidence from this paper that possibly the crises following thyroidectomy may be associated with hypoglycemia, although the whole mechanism is extremely obscure at this time.

Richard Bardon, M.D.

PEDIATRICS

THE EFFECTS OF SUSTAINED PITUITARY ANTIDIURESIS AND FORCED WATER DRINKING IN EPILEPTIC CHILDREN: A DIAGNOSTIC AND ETIOLOGIC STUDY: Irvine McQuarrie and D. B. Peeler (Jour. Clinical Investigation, 10:915, Oct. 20, 1931). The authors refer to work already reported on the relationship of water balance to the occurrence of convulsions in severely epileptic children, in which it was found that seizures, after having been brought under control by the production of a deficit in the body water, could be made to recur practically at will by the rapid reëstablishment of a positive water balance with pituitary antidiuresis. The possibility of utilizing the observed reactions of the severe epileptic to an enforced positive water balance as a diagnostic procedure in mild or obscure cases occurred to the authors early in their studies.

The experimental subjects used in their present study consisted of three groups of children. The first was made up of patients who gave personal histories more or less typical of "idiopathic" epilepsy, but had seizures at infrequent intervals. The second included cases with indefinite histories of "fainting spells" or "sleepy spells," but no history of generalized convulsions or true petit mal. The third group consisted of essentially normal children. The food given included the ordinary mixed diet, and special diets comparatively low in NaCl. Two of the epileptic patients were kept on a basic diet, consisting exclusively of heavy cream, sugar and water, the purpose being to limit the mineral intake to an extremely low level, except for short periods when carefully weighed amounts of NaCl were added for a special purpose. While under observation a complete study was made of the water and mineral balances for each patient.

To produce a positive water balance, water was given at the rate of 2 to 5 c.c. per kilogram of body weight per hour at either three- or four-hour intervals, simultaneously with sufficient amount of antidiuretic extract from the posterior lobe of the hypophysis (either pituitrin or pitressin P.D.) to prevent water diuresis. As a result of these studies the authors report that typical grand mal seizures can be induced within twelve to forty-eight hours in the epileptic, but not in the non-epileptic subject, by giving water at the rate of from 2 to 5 c.c. per kilogram of body weight per hour, while maintaining effective pituitary antidiuresis. This difference in response between epileptic and non-epileptic patients may be helpful in establishing the diagnosis early in an obscure case. Under the conditions of the experiments as described, dilution of the extracellular body fluids appears to be an essential factor in the induction of seizures since the administration of an amount of NaCl just sufficient to prevent this tends to interfere with their occurrence. The results presented lend strong support to the view that the mechanism for controlling semipermeability of the brain cell membrane is inherently defective in the epileptic patient.

C. A. Stewart.

THE POSTURAL TREATMENT FOR CEREBRAL HEMORRHAGE IN THE NEWBORN: Edwin A. Riesenfeld, M.D., New York, N. Y. (Arch. Ped., Vol. XLVII, No. 11, November, 1931). The presence of intracranial hemorrhage has been found as low as 10 per cent and as high as 60 per cent in all autopsies in stillborn infants and infants dying in the first few days of life. Among all the intracranial birth lesions, hemorrhages rank first as causing death.

The premature infant is particularly predisposed to intracranial lesions, due to the insufficient development of its tissues. When hemorrhage is extensive, usually associated with injury to the brain, the child is stillborn. In smaller hemorrhages, the child is stuporous. It cries with a peculiarly high pitched note. Respirations are irregular and feeble. Cyanosis, more or less constant, is observed. The infant nurses poorly or refuses to nurse at all. Convulsions occur frequently. In extensive hemorrhages, there may be bulging of the fontanel and separation of the sutures. A rise of temperature is often observed. The infant is usually pale. It appears as if in shock.

The generally accepted method of treatment has been confined to the administration of whole blood or blood serum, spinal tap, or the removal of blood or blood clot by entering the cranial vault. The last method is rarely resorted to today. Spinal tap, to relieve pressure and remove blood, is staunchly advocated by some, and as vehemently condemned by others. All new-born infants in whom the diagnosis of cerebral hemorrhage has been made should be placed in an upright position. The child should remain in the upright position for eight to ten days, or even longer should the symptoms of cerebral hemorrhage continue to manifest themselves.

Lessening in pressure readings in the cerebrospinal fluid in the upright position would tend to establish the rationale for the postural method of prophylaxis and treatment. In the upright position, the sagittal venous pressure is materially lessened as determined by animal experimentation. This would seem to be the logical position in dealing with bleeding from a torn cranial vein.

R. N. Andrews, M.D.

APPENDICITIS IN INFANCY: Benjamin Lipshutz, M.D., Philadelphia (Arch. Ped., Vol. XLVIII, No. 10, October, 1931). The highest mortality of appendicitis is at the extremes of life, over the age of fifty and under the age of three. Appendicitis in the nursling is rare.

The importance of the early diagnosis of acute appendicitis in infancy is very great, since the infection tends to rapidly diffuse throughout the entire peritoneal cavity. The general effects are usually severe, and toxemia may reduce the patient to a dangerous state within 12 to 24 hours. The defensive reaction of the peritoneum in the young is characterized by an extraordinary rapidity of absorption. The encapsulation and isolation of a peritoneal infection with dense hard organized adhesions is rather a process of adult life. Once the infection has advanced to the stage of an acute diffuse peritonitis, the outlook for recovery becomes very grave. Of all abdominal surgical emergencies, at least 50 per cent result from appendicitis.

Every infant or child that complains of vomiting and exhibits evidence of abdominal pain should be considered as a possible case of appendicitis. The association of vomiting with diarrhea is the unusual in appendicitis. Vomiting and constipation are the cardinal symptoms of peritoneal irritation.

Acute abdominal symptoms may have their origin in some thoracic lesion. In doubtful cases a careful emergency X-ray of the chest will often disclose positive pulmonary findings before they are evident on physical examination. It is a matter of common knowledge that patients with throat infections or upper respiratory tract infections occasionally develop severe abdominal pain.

If, after a careful clinical survey of the patient, the diagnosis remains uncertain, it is a safe clinical bet that the odds of safety are clearly on the side of surgical intervention.

R. N. Andrews, M.D.

SURGERY

PHRENICECTOMY IN PULMONARY TUBERCULOSIS—INDICATIONS FOR THE OPERATION AND POST-OPERATIVE ACCIDENTS: Roger Pigeon (Revue de la tuberculose, 1931, XII, 842). The ideal indication is the fibrosing case in which pneumothorax cannot be used. The fibrosing tendency of such a lesion is shown in various ways: by clinical signs indicating the lack of any tendency to rapid progression, by well known X-ray signs, such as homogeneous shadows due to pleural thinkening, diminution of intercostal spaces, unilateral deviation of the trachea, lack of mobility in the diaphragm when the patient is made to breathe deeply, a scalloped diaphragm indicating adhesions, which prevent a satisfactory pneumothorax, finally the costophrenic angle obscured, retraction of the ribs, bronchiectasis, dextro- or sinistrocardia. Some authors, however, consider complete pleural symphysis a contra-indication.

But not all cases showing a tendency to fibrosis are suitable for phrenicectomy. The typical case in which early and satisfactory results are obtained is the one characterized by a recent ulcero-fibrous lesion. In the presence of a lesion of this type the size of a hazelnut or up to the size of a walnut which has appeared without warning, the physician should not delay too long waiting for the spontaneous retrogression which rarely occurs; when a cavity the size of a mandrin has developed it is often too late. Even smaller cavities, if surrounded by organized fibrous walls, may prove refractory to the treatment. Again, it is necessary that the cavity be surrounded by more or less healthy tissue. It is foolish to expect results from phrenicectomy in extensive consolidated caseous areas such as are encountered in tuberculous pneumonemia, especially in the right upper lobe. Finally, the lesion should ordinarily be unilateral though small cicatrized lesions on the opposite side may be present.

In brief the principal indication for phrenicectomy is the presence of an ulcerofibrous lesion with little tendency to rapid evolution and not secreting profusely. It may be at apex or base, on the right side or the left. It should be relatively recent, well localized, usually unilateral and not amenable to pneumothorax. The immobility secured is roughly proportional to the length of the portion of nerve removed.

Postoperative accidents.—The authors note the occurrence of headache, vomiting and tachycardia as of rather frequent occurrence though of not more than a day's duration, immediately following the operation. Spread of the lesion to the other side occurs in certain cases. In others with extensive though unilateral fibrous lesions, dyspnea has been considerably increased, especially if the elevation of the diaphragm has been considerable.

Hemoptysis has occasionally developed when not previously present. The writers have not observed gastric complications though other writers have reported them. Possibly certain abdominal symptoms may be due to change in intra-abdominal relations following the operation.

Cardiac complications have been reported by various writers but serious ones are rare. Naturally if a marked increase in the height of the diaphragm is secured, more work will be required of the heart and the operation should not be attempted in those whose hearts are already overtaxed. Bilateral phrenicectomy has been used by several physicians in the treatment of basal cavities but the writers do not seem to have had any experience with it and urge caution in its use.

Phrenicectomy may be used in association with pneumothorax, apicolysis or thoracoplasty. In pneumothorax it is indicated when adhesions at the base limit the completeness of the collapse. It is also of value in certain cases of spontaneous pneumothorax. The use of pneumothorax on one side and phrenicectomy on the other side for a basal cavity is mentioned. The writers quote with some approval Wirth and Vonjaski, as recommending phrenicectomy before pneumothorax when a workman's time or resources are limited. They claim that the interval between refills may thus be lengthened. The use of phrenicectomy either before or during apicolysis and thoracoplasty is also approved.

A. T. Laird.

EFFECTS OF POSTURE AND THE DIAPHRAGM AND MEDIASTINUM WITH REFERENCE TO PHRENICECTOMY: Lincoln-Fisher (Amer. Rev. of Tuberc., XXIV, p. 57, July, 1931). In the first portion of the paper the author reviews the use of the recumbent postural positions in the treatment of tuberculosis. He describes the use of apparatus in the study of the effects of position on the diaphragm and mediastinum with the aid of the fluoroscope. He lists the different points from which the measurements are taken.

He states that when the lateral position is first assumed there is shown in the normal an initial increase in the excursion of the diaphragm which is most marked on the dependent side. After a period of thirty minutes to one hour this increased excursion is decreased somewhat, more so on the dependent side. The excursion of the diaphragm is more in the lateral recumbent posture than in the erect position.

Concomitant with the increased excursion is a rise of the diaphragm on the most dependent side. At the end of the hour there is a farther rise in the diaphragm of the dependent half, accompanied by a partial recovery and rise of the upper half. The dependent half of the diaphragm assumes a higher position and the upper half assumes a lower level in the lateral posture than with the patient standing erect. The heart and the mediastinum fall toward the dependent side, shifting as much as 5.3 cm. in one hour. The average shift was greater with the patient on the left side. After phrenicectomy these findings are accentuated. When the paralyzed half of the diaphragm is most dependent there is an increase in the elevation of the paralyzed half, and then the unparalyzed half of the diaphragm when uppermost assumes a lower level and has increased excursion. This persists to some extent while erect. The heart and mediastinum show a tendency to fall more to the paralyzed side. At times postoperatively the patient complains of trouble in breathing when lying on the good side.

The author then shows a number of tables of fluoroscope experiments to show his contentions in regard to the position of the diaphragm in the different positions.

In the summary the author states:

1. The diaphragmatic excursion is generally greater if the patient is in the lateral recumbent posture, decreasing somewhat before the end of an hour.
2. The lateral recumbent posture ascent of the de-

pendent and descent of the upper hemidiaphragm occurs initially, both halves assuming a somewhat higher level by the end of an hour.

3. The heart and mediastinal contents shift towards the dependent side, the average displacement being greater to the left than to the right.

4. Following phrenicectomy there is descent and increased excursion of the contralateral hemidiaphragm, which is accentuated and tends to persist in the lateral posture. The dependent half is forced still higher into the thorax by the pressure of the abdominal viscera.

5. Displacement of the heart and mediastinum due to posture is greater in phrenicectomy.

6. Increased respiratory labor following phrenicectomy requires a compensatory overaction of the contralateral hemidiaphragm forming the paralyzed half. This hyperactivity is less as the postoperative interval lengthens.

7. Posture rest on the better side following phrenicectomy is inadvisable.

8. The lateral recumbent posture increases diaphragmatic breathing, a change favoring rest of upper lobe lesions. Following phrenicectomy the scope of postural rest is widened, especially for patients with unilateral involvement or with only apical disease in the contralateral lung.

Since reading this article I have instituted the postural treatment in some of my cases of phrenicectomy. In those in which I have used this I have had the following complaints:

1. That when first used there is an increase in coughing and in the amount of sputum expectorated.

2. That after a time this subsides and the patients in general feel much better.

No remarkable results have been as yet shown.

J. J. Rouse, M.D.

THE MENACE OF METHYL ALCOHOL

The dangers from the use of methyl alcohol have increased because the prohibition of alcoholic beverages has led to the substitution, in ignorance or unwittingly, of methyl alcohol. The danger has been increased by its use in automobiles as an anti-freezing agent in radiators of motor cars. In addition to the deliberate or the unsuspecting imbibition of the harmful methyl alcohol there are the dangers not only of inhalation of its vapors but also of its possible absorption through the skin. From studies on animals, it has been estimated that approximately 1 ounce of methyl alcohol repeatedly in contact with the human body, under conditions favorable to retention and evaporation, constitutes a threat to well-being. It has also been estimated on the basis of experiments on monkeys, that the vapors of one ounce of methyl alcohol entering the human body constitute a threat to life even when the exposure is distributed over two or three days. (Jour. A. M. A., December 5, 1931, p. 1710.)

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

Electrotherapy and the Elements of Light Therapy. Richard Kovacs, M.D. Clinical Professor and Director of Physical Therapy, Polyclinic Medical School and Hospital, New York, etc. 528 pages. Illus. Price, cloth, $6.50. Philadelphia: Lea & Febiger, 1932.

Proceedings of the Twenty-fifth Annual Convention of the Association of Life Insurance Presidents. 278 pages. Illus. New York: The Assn. of Life Insurance Presidents, 1931.

Annual Report of the Surgeon General of the Public Health Service of the United States. For fiscal year of 1931. 354 pages. Illus. Price, 85c, cloth. Washington: U. S. Government Printing Office.

Courts and Doctors. Lloyd Paul Stryker. General Counsel for the Medical Society of the State of New York. 236 pages. Price, cloth, $2.00. New York: The MacMillan Company, 1932.

General Surgery. The Practical Medicine Series. Edited by Evarts A. Graham, A.B., M.D. 804 pages. Illus. Price, cloth, $3.00. Chicago: The Year Book Publishers, 1932.

General Medicine. Practical Medicine Series, 1931. Edited by George H. Weaver, M.D., et al. 814 pages. Illus. Price, $3.00. Chicago: The Year Book Publishers.

Physicians' Manual of Birth Control. Antoinette F. Konikow, M.D. 245 pages. Illus. New York: Buchholz Publishing Co., 1931.

Primer on Fractures. Coöperative Committee on Fractures, American Medical Association. 63 pages. Illus. Price, $1.00. Chicago: American Medical Association Press, 1931.

FEMALE SEX HORMONOLOGY: A Review. By William P. Graves, A.B., M.D., F.A.C.S., Professor of Gynecology at Harvard Medical School. First Edition. Cloth. Price, $3.50. Pp. 131, with illustrations. Philadelphia: W. B. Saunders Company, 1931.

A contemporary of Virchow or of Pasteur may have looked into the fields opened by those men and seen potentialities equal to those which, "with wild surmise," appear to modern physicians in the subject of female sex hormonology. The prospect is fascinating, rich and stimulating. The facts known are many, and conjecture and theory concerning them has greatly increased the complexity of the situation. Attempts at reviewing the subject are numerous; this effort of Graves' is conspicuous among them by reason of its clearness. He achieves this clearness by his arrangement of material, by freedom from digression, and by a glossary which adequately defines and describes the terms of a rapidly growing, special vocabulary. In this glossary certain original investigations in hormonology are specially designated as historical landmarks, and will thus serve as guides to the reader in this field.

The book, as indicated by the author, was "originally undertaken to furnish a concrete picture of a complex subject" for his lectures. It is designed, as he says, for the student with little previous knowledge of the subject. It is this point which makes the book so valuable, for the student who may have had previous knowledge of the subject will almost certainly be more hopelessly lost than one who had none; the author indicates this—with another connotation, however—when he says that "as the game proceeds the pawns will necessarily be differently placed." An illustration of this idea is seen in the work of Hartman concerning menstruation, in which the previous conception of that process is completely changed from a passive to an active one, with a special pituitary hormone producing it independently of either the follicle-stimulating or the luteinizing principle.

There are twelve chapters: Early history; Sexual cycle in animals; Sex cycles in the ovary; Sex cycle of the human uterus and its correlation with that of the ovary; Search for the hormones of the ovary; Discovery of the hypophysis as an agent in the sexual and reproductive cycles; Hormones of the anterior lobe identified; New theories regarding menstruation; New theories regarding parturition; New theories regarding lactation; Organotherapy.

E. C. HARTLEY, M.D.

SIMPLE LESSONS IN HUMAN ANATOMY. B. C. H. Harvey, M.D., Professor of Anatomy, University of Chicago, American Medical Association, 1931. Price, $2.00.

This moderate sized inexpensive volume is a compilation, somewhat elaborated and with numerous illustrations added, of a series of articles by the author which appeared in *Hygcia.* The material was prepared for the lay reader and is presented in an interesting manner (a supposedly impossible task), the functions of the various parts of the body being correlated. The volume would be suitable for the high school curriculum.

C. B. DRAKE, M.D.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

WANTED—Location in Minnesota by Northwestern graduate—age 29. Interned at Ancker Hospital, St. Paul. Desires general practice in town of 1,500 or more, convenient to hospital facilities. Address D-155, care MINNESOTA MEDICINE.

FOR SALE—Small rural hospital. All modern. Worth $25,000. Will sacrifice for $16,000. Instruments and equipment included. $5,000 cash, balance terms. Address D-157, care MINNESOTA MEDICINE.

OFFICE SPACE for physician and dentist, corner location, Hennepin Avenue and 28th Street, Minneapolis. Address J. R. Hunsaker, West High Pharmacy, Hennepin at 28th, Minneapolis, Minn.

WANTED—Position as office assistant to physician. Address Gladys Sundquist, 1865 Goodrich Avenue, Saint Paul, or telephone Emerson 9570.

FOR SALE—Office equipment including X-ray. Location in Minnesota town of 1,400 people. Average income of over $5,000 yearly for the past eight years. Unopposed. Specializing. Address D-150, care MINNESOTA MEDICINE.

THREE GENERATIONS of experience in grinding, specializing in fine surgical instruments. Prices, reasonable. Schwarz Grinding Service, Foot-Schulze Bldg., 128 10th St. E., St. Paul. Telephone, Midway 9939.

PHYSICIAN WANTED—In northern Minnesota town, population six hundred. No competition, large territory. Equipped office of former physician can be rented. Write D-160 care MINNESOTA MEDICINE for information.

MEDICAL AND X-RAY TECHNICIAN desires position. Thoroughly trained and experienced. Also Basal Metabolism, lamp treatments, etc. Good references. Address D-161, care MINNESOTA MEDICINE.

WANTED—Position as office assistant to physician in St. Paul. Three years' stenographic experience, and acquaintance with medical terms. Address D-162, care MINNESOTA MEDICINE.

OPERATIVE TREATMENT OF JOINT TUBERCULOSIS*

MELVIN S. HENDERSON, M.D.
Rochester, Minnesota

TUBERCULOSIS of bones and joints in America is on the wane. This is fortunate, but it does not bring solace to the unfortunate person who is afflicted, and he stands before the medical profession as a challenge to find measures of relief.

Joints are composed of bone, cartilage, ligaments, and the true joint lining (synovia). Usually when tuberculosis involves any given joint both bone and synovia are affected. Involvement of the joint lining only, or of the shaft of the bone only is rare. Tuberculosis of a joint is always preceded by the presence of the disease elsewhere in the body. The usual channel of entry for the bacillus is either the air passages, and so into the nodes at the base of the lung, or the intestinal tract, and thence into the nodes of the abdominal cavity. From these nodes the bacilli enter the blood stream, and are deposited in the skeletal structures and in the joints. In reality, therefore, we are dealing with a systemic disease, and regardless of whether conservative or operative treatment is to be accorded the affected joint, constitutional treatment is of primary importance. Perhaps the greatest danger of operative treatment of tuberculous joints is that all the attention may be focused on the joint, and the general and hygienic measures so essential to treatment may be neglected.

Tuberculosis of bone has been recognized and treated for many years, and it would seem that the results obtained and recorded in large institutions and in organized clinics would be available as definite guide posts, by which treatment could be directed. One can picture the dilemma of succeeding generations of young physicians and surgeons who assume the difficulties of treating such patients. When these surgeons visit such a center as Leysin, Switzerland, where Rollier carries on his treatment, they find him using only conservative measures, and when they visit the clinic conducted by Hibbs at the New York Orthopedic Hospital, they find a diametrically opposite stand, since he advocates operative treatment. After all, the results obtained should control the type of treatment, and out of the haze of conflicting views certain facts are gradually accumulating for the guidance of future generations. A famous man's personality and the glamour surrounding him may cause the over valuation of certain methods advocated by him, but trial by others is the acid test.

The treatment of tuberculosis of the joint may be classified under two headings: conservative and surgical. I shall speak today of the operative treatment, but before I embark on any consideration of the subject I wish to make it clear that my remarks will be confined to tuberculous joints of the adult. I am aware that there is a tendency to advance the line of operative attack to include the diseased joints of children, and although because of frequent disappointment in the conservative treatment for children, I am fundamentally in sympathy with this trend, there are many factors to be considered. The child's time is not so valuable as that of the adult, he has no responsibilities, and often, in healthful and happy surroundings, overcomes the disease. Institutions are readily available for the child, in which he may stay indefinitely, whereas this is not true of the adult. My experience has been chiefly with the adult. My comparative inexperience with the disease in children and lack of records of sufficient end-results with children on which to base my opinion lead me to be unwilling to take any definite stand. At The Mayo Clinic the majority of children are treated by conservative measures.

---

*From the Section on Orthopedic Surgery, The Mayo Clinic, Rochester, Minn. Read before the Mississippi Valley Conference, St. Paul, Minnesota, September 21 to 23, 1931.

I firmly believe, that taken by and large, the end-results in the adult, following even carefully controlled and protracted conservative or non-operative treatment of tuberculosis of joints, have been poor. In America people are loath, even if the opportunity is available, to submit to prolonged recumbency, heliotherapy and so forth. They become discouraged, accept their braces as necessary evils, and get along as best they can. For many years we have seen, in The Mayo Clinic, numbers of adults with tuberculosis of the joints who have been wearing braces and appliances for long periods with no appreciable curative results. I do not intend to convey the idea that adult patients never get well under conservative measures, for I believe they occasionally do. If, after years of conservative treatment, a tuberculous joint will become ankylosed, it is looked on as a triumph for conservative measures. If the same can be accomplished in as many months through operative measures, why waste all the time? Operative measures either should eradicate the disease entirely, or as nearly as possible. It should also induce ankylosis, with the minimal risk to the patient of death or dissemination of the tuberculosis. The chances of success will vary with the patient and with different joints. The structure of the joint and its contiguous structures have a bearing on the outcome. It is manifest that although a patient may have a tuberculous knee that should be resected, if he has active tuberculosis of the lungs and bilateral renal tuberculosis, operative measures are not indicated. It is also self evident that the same thorough resection and eradication of disease that can be carried out on the knee cannot be carried out on the spinal column, with the spinal cord coursing down the canal made by the very bones affected.

It is impossible to speak at any length of the methods best suited to the different joints. The upper extremity, since weight-bearing is not required of it, lends itself more readily to conservative treatment. However, the wrist and the elbow, and the ankle, for various reasons, are not readily treated by operation, and the percentage of cases of tuberculosis of the ankle that come to amputation is higher than that of any other joint. The knee, spinal column, shoulder, and hip, in the order named, are suitable for operative procedures, and I shall briefly discuss the various types of operative measures that may be employed.

SELECTION OF THE PATIENT

Patients for operative treatment should be beyond the age of puberty, should be free of active pulmonary disease, should not have tuberculosis of the genito-urinary tract, and should be in good general health. A tuberculous kidney may have to be removed before the joint can be operated on, for the former is a vital organ, and if the disease is localized to one kidney, that organ should be removed before the opposite kidney is affected. Radical operations should not be done if draining sinuses are present. Exceptions may be made on these points only for very good reasons.

Each patient must have a thorough physical examination before radical surgical measures are instituted. Roentgenograms of the lungs should be made; also the urine should be subjected to tests, including microscopic examination, and if blood or pus is persistently present, cystoscopic examination should be made. The temperature should be noted and examination of blood made. In adults particularly, syphilis should be ruled out. It is only by such careful selection of patients that the mortality rate can be kept within legitimate limits. In the series of more than 600 cases in which operation has been performed at the clinic, the operative mortality rate is less than 1 per cent. A follow-up study over a term of years, of these same patients who recovered from the operation, shows that even in this selected group the mortality is high, 8 per cent in cases of tuberculosis of the knee, and 20 per cent in cases of tuberculosis of the spinal column. Dissemination of the tuberculosis is the cause of death in most cases, but the comfort derived from the result of the operation is well worth while. Most of the patients who died lived from four to eight or more years after the operation, and there is reason to believe that their lives were longer and their existence much more comfortable by virtue of having undergone operation than they otherwise would have been.

TYPES OF OPERATION

Aspiration and injection of various solutions.—In the main, the results of aspiration followed by injection have been sadly disappointing. The knee is the only joint anatomically suited for such treatment, and even here evidence has not been presented that warrants its continuance. However, aspiration or biopsy for the purpose of diagnosis by laboratory examination, and by inoculation of animals, is a definitely established and useful procedure.

Amputation.—Removal of an extremity should be resorted to only for definite reasons. If, for example, a patient has persistent draining sinuses from a knee, with so much destruction that the usefulness of the joint is hopelessly destroyed, or if pain is very severe and wearing, or if a patient already is burdened with tuberculosis in the lungs, kidneys or abdomen, amputation, although only a palliative measure, may be best. Economic conditions surrounding the patient may also be a big factor. Tuberculosis of the ankle often compels amputation, because of its prolonged course, and because of poor response either to conservative measures or to procedures intended to bring about ankylosis. Advanced destruction in the knee of an elderly person also usually is best treated by amputation.

Operations leading to ankylosis or fusion.—In the adult with tuberculosis of a joint the best thing that can happen is sufficient destruction of the cartilaginous surface to bring about bony union. Spontaneous recovery, with permanently good function, in the adult is so rare that it does not pay to wait for it. In some chronic cases sufficient comfort is secured through conservative measures to enable the patients to get along, but exacerbations are common, and they usually lead to the patient accepting an operation to produce ankylosis. Arthrodesis, or fusion, is particularly applicable to the knee and shoulder, although, with modern improved technic, the hip is fast becoming more amenable to this type of operation. The operation consists in exposing the diseased surfaces of the joints, removing all the affected cartilage and bone until healthy bone is thoroughly exposed, removing also all the synovia possible, and finally reshaping and fitting the ends of the bone so that they may be held firmly together until union occurs. The finer points in technic vary, naturally, with different surgeons. In the spinal column, this type of radical operation cannot be done, but it is possible to fuse the posterior portions of the vertebræ, and to extend such fusion well above and below the affected vertebræ, by the plastic method of Hibbs or by the method of bone transplantation of Albee.

Experience with these types of operation in The Mayo Clinic has extended over many years, and the results justify adherence to the principle of radical operation, in selected cases, for tuberculous joints of adults. In 1927 we reported the results in 211 cases in which arthrodesis for tuberculosis of the knee was performed, and in 1928 I reported a series of 301 cases in which the fusion operation for tuberculosis of the spinal column was carried out. The results were good, all things considered, and many patients who had dragged themselves about for years, with the aid of crutches and braces, were enabled to discard these entirely and enter again a normal life. In a smaller series of cases in which the hip joint was involved, not as yet reported, the same proportion of satisfactory results was obtained. A painless, useful, stiff joint is preferable to a useless, more or less movable joint, and when the patient is given an explanation as to what he may expect from either conservative or operative methods, it is seldom that he fails to elect the latter.

SUMMARY

Conservative treatment has its greatest field of usefulness in treatment of children; operative treatment has its greatest field in treatment of adults. If the adult patient is in good general condition, and there are no draining sinuses, fusion should be produced when practical. The knee, spinal column, shoulder and hip are anatomically suited to a fusion operation. Each patient constitutes an individual study, and generalities, that may be true in the main may not be applicable to the individual.

OBSERVATIONS IN THE DIAGNOSIS OF GALLBLADDER DISEASE*

Max H. Hoffman, M.D.
Saint Paul

GALLBLADDER disease is said to be the most common organic cause of organic digestive disturbances in the adult. It has been roughly calculated that over 20 per cent of all adults presenting symptoms referable to the digestive tract have pathology in this organ.[1] This figure is not difficult to believe, when we note that the statistics of several series of routine post-mortem examinations show that 4 to 10 per cent[2] of all cases have gallstones.

The diagnosis of cholecystic disease is often not easy. Atypical clinical pictures are very confusing to the clinician and frequently it is impossible to make a definite diagnosis. Since the introduction of the Graham-Cole method of visualizing the gallbladder, a renewed interest has been stimulated in an attempt to make an earlier diagnosis of cholecystic disease. This method of examination has proved itself to be a great aid to the diagnostician. Much has been claimed by certain writers for the value of Meltzer-Lyons method of studying the biliary fluid by means of a duodenal tube. Many who have given this test a fair trial feel that its value can be seriously questioned.

This study represents an analyses of 155 cases that presented evidence of a sufficient degree to warrant gallbladder removal. An attempt was made to determine the accuracy of the diagnosis and the reliability of various diagnostic procedures, such as X-ray and physical examination, and symptomatology. All the patients in this group were operated upon by Dr. Arnold Schwyzer, and the pathological notes were taken from his operative descriptions and the laboratory reports.

The gallbladder was said to be diseased if any of the following observations were made:

1. Thickening of the wall or changes in color or texture indicating fibrosis.
2. Stones in the gallbladder or in the cystic duct.
3. Changes in the mucosa indicating inflammation or cholesterin deposits.
4. Thickening of the gallbladder bed with changes in the adjacent liver tissue.
5. Round cell infiltration in the gallbladder wall.
6. Positive cultures in the bile or gallbladder wall.

This is, of course, a classification devised for this study, and in no sense is it to be construed as the final word in classifying diseased gallbladders. It is often difficult to say just when a gallbladder is pathological. Does a positive culture with a normal histological structure indicate disease?[3] Is thickening of the region around the opening of the cystic duct, with the remainder of the gallbladder normal, an indication of pathology?

One hundred and seventeen of the patients operated upon had stones in the gallbladder or in the cystic duct. This is 76.5 per cent of all the cases. One had a carcinomatous gallbladder, two had benign tumors, and three empyema. The remainder, diagnosed as being pathological, had one or more of the findings listed above. Eleven cases (7 per cent) were called normal or questionable. For purposes of discussion, we will separate the pathological cases from the group that showed no pathology at the operation.

SYMPTOMATOLOGY

Without question the most important single diagnostic procedure is the securing of a careful history dating back to the first appearance of digestive disturbances or pain. The patient often needs considerable prodding in order to remember the mild pains and digestive upsets that occurred a number of years before. Complete freedom from distress of any kind may be present for years after the initial attack.

The symptomatology of gallbladder disease has its origin either in the over-distended gallbladder itself or by reflex or direct action of the diseased gallbladder on the adjacent organs, notably the stomach, pancreas, and intestinal tract. Alvarez[4] "reverse peristalses syndrome" plays a very prominent part in the production of the discomfort.

---

*Thesis presented before the Minnesota Academy of Medicine, October 14, 1931.

Pain.—Pain is the outstanding symptom that brings the patient to the physician. Although it appears that severe pain is a late development in the course of the disease, the earlier digestive symptoms are often not sufficiently severe to cause the patient to seek relief. Several of our group gave a history of having had the first attack twenty-five to thirty years before coming to the office, the intervening period having been free from any severe pains. Many gave a history of periods lasting several years between attacks that were free from symptoms. The intensity varied from slight pains bordering on discomfort to very severe colicky attacks that required large doses of morphine for relief.

Most of the patients complained of pain in the upper abdomen. In our group, six patients had no pain at all. Sixty-one patients (40 per cent) complained of pain in the upper right abdomen, below the costal margins, and radiating around to the back. All of these individuals had pain occurring in attacks. This, of course, is the most typical type of gallbladder pain and corresponds to the textbook description of pain occurring in an attack of gallbladder colic. Forty-three had pain located in and to the right of the epigastrium that did not radiate to the back. In many of these the pain also came on in attacks, but much less frequently than in the group in which the pain was in the right hypochondrium.

It was noted that frequently in the early attacks, the pains were limited to the epigastrium, and in the later attacks it shifted to the right hypochondrium and back. In one patient it was limited to the right shoulder, in one to the interscapular region, and in five the pain was in the lower right abdomen. The remainder of the patients had pain mostly in the right abdomen, or across the abdomen, but not well localized. The frequent association of gallbladder disease with appendicitis and duodenal ulcer must be borne in mind. In our group we had no cases in which the pain was limited to the left side of the abdomen.[5] This type of pain has been described and is explained either as referred pain or pain due to the spasm of the pylorus that so frequently occurs in gallbladder disease.

It is well known that attacks of pain occurring at night and awakening the individual from sleep are frequently a part of the history of those who suffer from duodenal ulcer. In fact it occurs so frequently that it is considered almost pathognomonic of this disease. For a number of years Dr. Arnold Schwyzer has emphasized the importance of night pains, occurring in gallbladder disease, especially those pains occurring after 2 A. M. There has been an attempt to explain this phenomenon as being the result of small stones floating into the cystic duct when the patient assumes a horizontal position. We found that one-third of our patients had night pains of the type described above. Many of them, however, occurred before 2 A. M. We also found that it occurred just about as frequently in those who had cholecystitis without stones as in those patients who had stones.

It would seem that night pains could be much better explained by the failure of the diseased gallbladder to empty properly at night when the stimulus for emptying, *i.e.*, gastric contraction and food ingestion is withdrawn. The gallbladder, in failing to empty, becomes over-distended and causes pain.

Dyspepsia.—Dr. Alvarez[4] has called attention to a group of symptoms that he has termed "the reverse peristalsis syndrome." These symptoms are nausea, vomiting, belching, bloating and pyrosis. Although they are present in many states causing digestive disturbances, including that large group termed functional indigestion, he believes this syndrome is often an early finding in cholecystic dysfunction. In our group, six patients had no definite history of pain, but presented one or more of the above complaints.

Nausea and vomiting were present in slightly over one-third of the cases, but in the great majority only during an attack, and it was usually accompanied by bloating and belching. It was rather surprising to find that relatively few patients carried the digestive disturbances through the periods between the attacks. Those that had trouble during this period were bothered mostly with bloating and belching. Nausea and vomiting were conspicuously absent.

We were unable to find that there was any particular food that uniformly caused these patients distress. Fats are said to be eaten with difficulty, but in our group there was no good evidence for this statement. Nor were we able to find that any particular food, or foods in general were capable of producing an attack. The patient is always searching for a cause, and usually ascribes it to something that was eaten in the previous meal.

Physical Findings.—The only physical findings that seem to be of any importance are tenderness, palpation of the enlarged gall bladder, and jaundice. Of these, tenderness is by far the most frequent and most important sign. It was present in about half (78) the cases of our group, usually during and for a short time after the attack. In seventy-four of these cases it was in the upper right abdomen. In four cases it was across the upper abdomen. About half of the group had no history of ever having had any tenderness. Two patients had muscular resistance without soreness. When present, it is an extremely valuable finding, but its absence should not mislead the clinician in his search for gallbladder disease. When ordinary palpation fails, tenderness can often be elicited by having the patient sit up and lean forward; then, with the physician behind, the examining fingers can be pressed deeply under the ribs.

The gallbladder was palpated in only three patients, two having empyema and one carcinoma. Some writers[6] claim to be able to feel the gallbladder in a large percentage of their cases. It would seem, however, that the location of this organ, together with the softness of the tissues around it, would make it very difficult to palpate. When it is palpable, it always means that a pathological condition is present.

It is generally believed that jaundice is a frequent occurrence in gallbladder disease. Only eleven patients (less than 8 per cent) had jaundice at one time or the other. In three cases it was questionable. No routine examination was made to determine the presence of bilirubinemia.

CHOLECYSTOGRAPHY

The Cole-Graham method of examining the gallbladder by means of a dye and X-ray has superseded the older indirect X-ray examinations. This method is far from infallible, and its accuracy depends a great deal upon the experience of the interpreter and the technic used.

There are also sources of error that cannot be controlled. If we recall that the appearance of the dye in the gallbladder depends upon its first being absorbed from the intestinal tract and then excreted by the liver, we can understand that the concentration of the dye does not always represent the functional state of the gallbladder. For that reason we cannot accept the lessened intensity of the shadow as always indicating disease when the oral method is used.

However, in spite of the factors that affect the efficiency of this test, it is a valuable aid to the diagnostician, and taken together with the clinical picture, it has markedly increased the percentage of correct diagnoses. It should be borne in mind that a failure of the dye to appear does not always mean gallbladder disease. Nor does a normal shadow always signify a normal gallbladder.

Cholecystographic studies were made in 122 cases by the oral method. A diagnosis of pathological gallbladder was made in ninety-eight and fourteen were called normal. In the group diagnosed as being pathological, the percentage of correct diagnoses according to the cholecystographic criteria of pathology was as follows:

1. Nonvisualization of the gall bladder shadow. 40 cases. 29 showed stones, 10 had other definite pathology, and one was normal.
   Percentage of correct diagnoses........................97.5%
2. Diagnosis of stones, *i.e.,* stones visualized. 40 cases. 38 showed stones, one had other pathology, one was normal.
   Percentage of correct diagnoses........................95%
3. Faint visualization. 13 cases. 4 showed stones, 7 had definite pathology, and 2 were normal.
   Percentage of correct diagnoses........................85%
4. Irregular filling. 5 cases.
   4 were normal, one was pathological.
   Percentage of correct diagnoses........................20%

Of the group diagnosed as being pathological, according to the Graham-Cole test, eight were normal and ninety pathological at operation: a percentage of correct diagnoses of 92 per cent. The greatest number of errors occurred in the group where the gallbladder was called abnormal because of an irregular filling. In that group the diagnosis was correct in only one out of five cases. Obviously, then, an irregular shadow is a poor basis for making a diagnosis of pathology.

In the first group, where the diagnosis of pathology was based on the nonvisualization of the gallbladder shadow, we had a very high percentage of correct diagnoses, 97.5 per cent; a figure higher than the true value of this finding would warrant. On several occasions we have failed to secure a filling of the gall bladder on the first examination, and later a normal response was present when the examination was repeated.

A diagnosis of cholelithiasis can be made only if the stones are visualized. Usually there is not much difficulty in interpreting stone shadows. However, there are two sources of error that must be guarded against. The negative shadows cast by cholesterin stones may be simulated very closely by bubbles of gas in the bowel. Frequently these negative shadows are called stones, but a little experience will usually enable one to differentiate them correctly. Another source of error occurs in those cases of stones in which the gallbladder fills very well with the dye. The intense shadow of the dye obscures the shadows cast by the stones. As Kirklin has pointed out, if the gallbladder is only partly emptied by a fatty meal, the shadows of the stones will be seen; but if it completely empties, the stones will often be missed.

There were fourteen cases in which the X-ray report indicated a normal functioning gallbladder. Of this group, six were definitely pathological. Three had pericystic adhesions of a degree and character that were not considered to be normal. Five were normal. Only one gallbladder in this group contained stones. If we were to exclude the group with adhesions as being pathological there would still be an error in diagnosis of 43 per cent. It is a well known fact that a pathological gall bladder can often concentrate the dye very well, even when numerous stones are present.

COMMENT

Of the entire group of 155 patients operated upon, eleven were considered as having no demonstrable pathology in their gallbladders, giving a percentage of correct diagnoses slightly over 92 per cent. Of the 92 per cent that showed disease, 81 per cent consisted of stones. This figure indicates pretty well that we have selected for operation a group that would present rather definite symptoms. From the standpoint of conservative surgery, this selection is very good, but it probably also means that we are making a definite diagnosis of gallbladder disease in only those cases that present a more advanced picture. Mentzer, at the Mayo Clinic, in 1,647 consecutive autopsy examinations, found that 37 per cent of the patients had cholesteroses of the gallbladder and 20 per cent of these had stones. If this figure gives us a true indication of the incidence of cholecystic disease, we must either be missing a large number of cases or must conclude that many of them do not ever produce symptoms, or possibly only in the late stages. It has been claimed that the early symptoms are those of digestive dysfunction; but we have been unable to find that these symptoms are in any way diagnostic: they merely make us suspect the presence of gallbladder disease. Some of our patients with advanced pathological changes had no digestive trouble except during and for a short time after an attack.

Pain is by far the most dependable finding, especially if it occurs in the upper right abdomen and at night after 2 A. M. In our group of pathological cases 34 per cent of the patients had night pains, whereas in the group of normal cases, only two patients, or 14 per cent, had similar pains.

The degree of pathology present and the intensity of the distress do not bear any definite relationship to each other. As a whole the patients with stones complain of more severe pain than those without stones. However, some with only a small amount of pathology had very severe symptoms while others with advanced changes had comparatively little.

Cholecystography is supposed to be a test of gallbladder function, and for that reason is considered by its discoverers to be especially valuable as a means of detecting early cases of gallbladder disease, where there are only slight pathological changes but considerable functional disturbance. If that were true, why do we so often find a good concentration of the dye with good emptying in the presence of stones and other disease? The answer to this question would indicate that stones may be present with a functionally intact gallbladder mucosa, and for a long time produce no symptoms. However, in spite of the deficiencies of this method, it has proved itself to be of inestimable value as a means of corroborating our clinical impression, and it often will make a definite diagnosis of gall-bladder disease where it was not suspected. In the absence of pain, one hesitates to make a diagnosis unless the cholecystograms indicate that there is some disturbance of the function of the gallbladder.

We have attempted to study the group of eleven cases where no pathology was found at operation by means of the follow-up notes on their records, and by sending them a questionnaire. They were asked if they still had pain and to locate and describe the character of the pain, the type of digestive trouble that was present, and whether or not they had achieved the relief that they had hoped for when they had consented to undergo an operation. Only seven questionnaires were returned. Of these, two were completely relieved of their symptoms. The gallbladder at operation in one of these cases was wrinkled and showed signs of recent distention with no other pathology. Another of this group who had a history of having had an operation for a duodenal ulcer, but who also had a positive Graham-Cole test, received no relief from the operation. The fourth case, before the operation complained of occasional diarrhea and abdominal pains. The pains were epigastric, occurred in attacks, and radiated to the shoulder blade. The Graham-Cole test showed an irregular shadow. At operation the gallbladder was normal. She stated in the questionnaire that the epigastric pain was gone, but the diarrhea and abdominal cramps were very severe. She did not think the operation helped her very much. Three of the seven patients who returned the questionnaire complained of diarrhea. It is not at all clear as to just what this means. It is well known that diarrhea fairly frequently accompanies cholecystitis and is explained by the decrease in the amount of acid secreted by the stomach. However, there does not appear to be any uniformity of opinion regarding the effect of gallbladder disease on gastric secretion, nor do we know a great deal about the effect of the gallbladder on the intestinal tract. The three other patients who returned the questionnaire did not obtain much relief.

Of the remaining four who failed to answer the questionnaire, the follow-up notes indicate that two had complete relief and two were not benefited. Three of the four had negative Graham-Cole tests; one was positive.

Of the eleven patients with a normal gallbladder, four had complete relief. Were these cases of functional gallbladder disorder, and is there such a thing as dyskinesia of the gallbladder? Dr. Boyden's work on the function of the gallbladder opens up a method of investigating this subject. It was also interesting to note that in this group of normal gallbladders there were a number of X-ray diagnoses of pathology, based on irregular filling, and one report of stones in which the shadow was cast by a gas bubble. With the increased experience that we now have in interpreting cholecystograms, most of them would be called normal.

As a whole the symptoms and signs presented by the group with normal gallbladders did not differ greatly from those in the definitely diseased group.

On the basis of this study it is felt that there is no group of symptoms that are at all characteristic or pathognomonic for all cases of gallbladder disease. The diagnosis is made primarily on the clinical findings, the dye test usually serving to give additional evidence. In the absence of very definite symptoms or positive physical findings, the diagnosis of gallbladder disease is always uncertain, and even with a typical history and X-ray findings all pointing to a diseased gallbladder, the laboratory will occasionally report—no pathology.

SUMMARY

1. This study is an analysis of 155 patients who presented symptoms that warranted the removal of their gallbladders.
2. The diagnosis was correct in slightly over 90 per cent. Stones were found in 77 per cent of cases.
3. Pain was considered to be the most reliable symptom. Night pains occurred in 38 per cent of the pathological cases, and, in the absence of a definite peptic ulcer history, is thought to definitely indicate the presence of gallbladder disease.
4. Digestive symptoms, although suggestive of gallbladder disease, are not of great diagnostic value.
5. The Graham-Cole test is of unquestionable value if the gallbladder fails to fill or if stones are visualized. The other findings are not considered to be very reliable.
6. The eleven normal cases were studied and were found to have about the same symptoms as the pathological cases. Four were completely relieved of their symptoms by the removal of their gallbladders.

AVERAGE OPTIMUM DOSAGE OF COD LIVER OIL

The Council on Pharmacy and Chemistry reports that at present the recommended dosages of cod liver oil differ widely. In part, the varying effects that have been reported may no doubt be explained by the unlike activity of different brands of cod liver oil. Thus, while the U. S. Pharmacopeia permits the claim that the product is biologically standardized if it contains 50 vitamin A units per gram as determined by the method given, certain brands now in New and Nonofficial Remedies guarantee a potency of 1,000 U. S. P. vitamin A units per gram, and none contains less than 500 units. The vitamin D potency of cod liver oil is probably still more uncertain, since no official method of assay has been adopted; hence it is most difficult to compare different brands of cod liver oil even if the vitamin D potency and method of assay are declared. In view of the foregoing situation, the Council referee in charge of cod liver oil and cod liver oil preparations believed that some effort should be made to ascertain the amount of cod liver oil that must be administered under ordinary conditions to obtain the effects attributable to cod liver oil. With a view to obtaining an expression in regard to the dosage of cod liver oil, an inquiry was formulated and sent to nineteen pediatricians. From the replies received it was noted that little reference is made to the possible physiologic value of the vitamin A of cod liver oil, and that the consideration of dosage is expressed wholly in relation to the vitamin D content, or in terms of its effects in overcoming the relatively obvious physical manifestations of rickets. In all the opinions cited, the authors apparently recognize the added value of vitamin A and prescribe cod liver oil in preference to plain viosterol. Viosterol is favored, however, but only as a supplement, such as cod liver oil with viosterol 10 D. Most of the pediatricians quoted seem to agree on a dosage of 3 teaspoonfuls daily as amply sufficient to prevent and cure clinically evident rickets. In contrast to the practice of physicians in former years, most of the pediatricians begin the administration of cod liver oil at a time when the growth begins to accelerate—if not within two weeks, then at least before the end of the first month—reaching the maximum dosage usually during the third and rarely later than the fourth month, thus usually aborting the rickets in its earliest incipience and hence obviating the use of large doses later. There appears to be general agreement that it is only during these first two or three months of most rapid growth that the child requires its maximum dosage of cod liver oil, which may be continued as an ample dosage on up to 2 years of age. The Council has decided that a dosage of 3 teaspoonfuls (12 c.c.; 3 fluidrachms) daily, may tentatively be set as the standard optimum dosage of cod liver oil for the average infant, at 3 months of age. (Jour. A. M. A., January 23, 1932, p. 316.)

DIAGNOSIS AND MANAGEMENT OF CORONARY ARTERIAL DISEASE*

M. H. Nathanson, M.D.
Minneapolis

William Harvey,[1] in one of his letters written in 1653, appears to have given the first definite account of a clinical picture associated with diseased coronary vessels demonstrated at autopsy. The following is quoted from Harvey's description: "I will add another observation, a noble Knight Baronet Sir Robert Darcie, about the middle of his age, did often complain of an oppressive pain in his breast, especially in the night time, sometimes fearing suffocation by a Paroxisme, he lead an unquiet and anxious life, using the Counsel of all Physicians, and taking many things in vain, at last the disease prevailing, he becomes cachectic and hydropick, and at last opprest in a signal-paroxism he died. In his Corps, in the presence of Dr. Argent, who at that time was President of the College of Physicians, and Dr. George, a rare divine, and a good Preacher, by the hindrance of the passage of the blood out of the left ventricle into the arteries, the wall of the left ventricle itself (which is seen to be thick and strong enough) was broken, and poured forth blood at a wide hole, for it was a hole so big that it could easily receive one of my fingers."

In 1768, Heberden[2] published his masterly description of a clinical picture to which he gave the name angina pectoris. Shortly after this, Jenner and Parry ascribed this condition to changes in the coronary vessels. An extensive literature developed, most of which consisted of attempts either to prove or disprove the relationship between coronary disease and angina pectoris. Thus Huchard[3] claimed that angina pectoris and coronary disease were practically synonymous, while Albutt[4] did not consider coronary sclerosis of any clinical significance, as the following statement indicates: "It is freely admitted that coronary disease may and for the most part does pursue its silent way without anginous or other storms." This uncertainty as to the clinical aspect of coronary sclerosis is shown by the fact that in most of the modern textbooks and systems of medicine there is no attempt to discuss coronary disease as a clinical entity. We have thus a common pathological condition which has been recognized for several hundred years, but which, apparently, still has no clearly understood and generally accepted clinical picture.

In order to study the clinical features of this condition an analysis was made of 113 cases from the Department of Pathology of the University of Minnesota.[5] All those included showed severe coronary disease with marked narrowing and partial obliteration of one or more large arteries, and usually definite fibrosis or softening of the myocardium. The clinical features discussed in the present report are derived from an analysis of the clinical data of this series of autopsies with the additional details obtained from observation of a group of clinical cases over a period of five years.

Age and Sex.—The average age at the time of death in the autopsied group was fifty-nine and two-fifths years. The youngest was thirty-two, and the oldest eighty-eight years. The age distribution is shown in the accompanying table (Table 1).

TABLE 1.—AGE AT THE TIME OF DEATH OF 110 CASES OF CORONARY DISEASE

Age	No. of Cases
30 to 39	2
40 to 49	17
50 to 59	28
60 to 69	45
70 to 79	15
80 to 89	3

There was a definite preponderance of males, the ratio of males to females being three to one.

Types of Clinical Picture.—The outstanding clinical feature was the tendency for the symptoms to occur in attacks. This was true in about 60 per cent, while in the remainder the symptoms were those of progressive heart failure, and acute paroxysms were not prominent. The attacks consisted of an oppressive pain in the chest in 75 per cent, and were localized to the abdomen in 25 per cent. Attacks of acute respiratory distress were present in about 10 per cent of the cases. On further analysis it was found that the clinical picture differed in two important respects: (1) as to size of the heart; and (2) as to presence or absence of congestive heart failure. Thus the heart was within normal limits as to size in 39.9 per cent and was enlarged in 60.1 per cent. Congestive heart failure, judged by clinical signs and postmortem findings, was present in 40.6 per cent and absent in 59.3 per cent.

---

*Read before the Northern Minnesota Medical Association, Moorhead, Minnesota, September 20, 1930. From the Department of Medicine, University of Minnesota, Medical Service, General Hospital.

From the standpoint of symptomatology the study of this autopsy material indicated that there were two distinct types of coronary disease: (1) a group in which the symptoms consisted of attacks of pain or acute respiratory distress, without evidence of congestive heart failure; and (2) a group in which the outstanding symptoms were those of congestive heart failure, dyspnea, cough and edema (Table 2).

TABLE 2.—TYPES OF CORONARY SCLEROSIS (113 AUTOPSIES)

	Per cent
Anginal Syndrome, liver congestion absent at autopsy	59
1. Heart normal in size	37
2. Heart enlarged	22
Congestive Heart Failure, liver congestion present at autopsy	41
1. Heart normal in size	2
2. Heart enlarged	39

Diagnosis.—The diagnosis of coronary disease with congestive heart failure will not be considered in this discussion. This type is intimately associated with hypertension heart and presents but few features which differentiate it from hypertension heart without coronary disease. Furthermore, the management is practically the same as for congestive heart failure from any other cause. This report is concerned only with that type of coronary disease in which the manifestations consist of paroxysms of pain or acute dyspnea unassociated with congestive heart failure. This group may be termed the anginal group, if it be understood that this term is used in a broad sense for attacks of pain or paroxysmal dyspnea of cardiac origin, with a tendency to sudden death. Since there are usually no diagnostic objective clinical features in this type, the diagnosis is frequently very difficult. The condition is easly recognized when the symptoms consist of the typical attack of angina pectoris, as first described by Heberden,[2] in 1768. However, attacks approaching this typical picture occur in not more than one-half of the cases. There is a great variety of atypical types, many of which present a clinical picture bearing little resemblance to the characteristic attack of angina pectoris. In such cases there are a number of points which require careful consideration, any or all of which may be of aid in arriving at a diagnosis. These diagnostic features may be enumerated as shown in Tables 3 and 4.

TABLE 3.—GENERAL DIAGNOSTIC FEATURES

1. Age
2. Sex
3. Family History
4. Associated Conditions
   a. Diabetes
   b. Hypertension
5. Habitus

GENERAL DIAGNOSTIC FEATURES

Age.—The average age at the time of death of 113 autopsied cases of coronary disease was fifty-nine and two-fifths years. Sixty-five per cent of the entire group were between the ages of fifty and seventy years. This corresponds to several other series which have been reported. The youngest patient that I have encountered with coronary disease proved by the electrocardiogram was thirty-five years of age and I have seen a considerable number between forty and fifty.

Sex.—In the autopsied group the ratio of males to females was three to one. This, however, includes also those terminating in congestive heart failure. In those presenting the anginal manifestations the preponderance of males was much greater, being about eight males to one female.

Family History.—Heredity seems to be an important factor in the etiology of coronary disease. I have seen frequent instances of several members of a family afflicted with the condition. A history of coronary disease in the family should have some bearing on the diagnosis.

Associated Conditions.—There are but two conditions which have a definite association with coronary disease—diabetes and hypertension. In a study by the writer of one hundred autopsies on diabetics,[6] it was found that coronary disease was present in 52 per cent of diabetics above the age of fifty, as compared with 8 per cent in non-diabetics of this age. Chart 1 graphically shows the incidence of coronary disease in diabetics and non-diabetics. Likewise, in hypertension heart at autopsy the incidence of coronary disease is about five times that of general autopsy material. The clinician therefore should consider more strongly the possibility of coronary disease when either diabetes or hypertension is present.

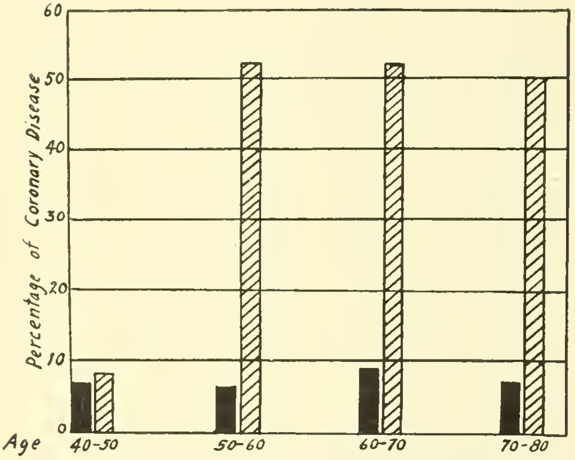

Chart 1.—Comparison of the incidence of coronary disease in diabetics and non-diabetics. (Striped columns, diabetics; solid black columns, non-diabetics.)

Habitus.—There is some correlation between the type of body build and coronary disease. The condition is extremely rare in the long, angular, asthenic type. It occurs most frequently in the short, broad, hypersthenic individual. Next in frequency is the tall, broad-chested type. It is true, however, that this condition may occur in an individual of normal habitus, but with less frequency. Levine and Brown,[7] in discussing coronary thrombosis, describe the type susceptible to this condition as a well-set person, somewhat overweight, often of considerable physical strength, who has enjoyed unusually good health.

SPECIAL DIAGNOSTIC FEATURES

Of greatest importance in the diagnosis of the anginal type of coronary disease is a careful and detailed analysis of the various features of the attack. When the major symptom is pain, there are certain characteristics so constant and typical of the pain of coronary disease that they are of great diagnostic import, while others are so variable and uncertain that they are of decidedly less significance.

TABLE 4.—SPECIAL DIAGNOSTIC FEATURES

A. Characteristics of the Attack
  1. Pain
    a. Site of pain
    b. Radiation
    c. Type of pain
    d. Factors inducing attack—exertion, emotion, large meals, flatulency
    e. Cessation of attack on rest
    f. Duration—condition between attacks
    g. Mental reaction
    h. Gastro-intestinal manifestations
    i. Reaction to nitrites
  2. Acute Dyspnea
    a. Sudden onset—usually nocturnal
    b. Examination of lungs, negative, or fine, moist râles or bronchial wheezes
B. Physical Examination of the Heart
  1. Enlargement—definite enlargement usually absent
  2. Auscultation—usually normal, first sound may be muffled or split
  3. Cardiac rhythm
C. Electrocardiogram—positive in about 70 per cent

Site of Pain.—In some cases the pain may be localized to any part of the chest or even to the back. However, it is usually situated behind the sternum, either at the upper or lower end. In about 25 per cent of the cases it is localized in the epigastrium. Pain limited to either the left or right side of the chest is infrequent as compared to the central chest location. A substernal or epigastric localization of the pain should always arouse the suspicion of coronary disease.

Radiation.—Radiation to the left shoulder, arm and forearm has been considered as characteristic for the anginal type of pain. An analysis of the autopsied and clinical cases indicates that this is not as prominent nor as constant a feature as has been supposed. In the records of fifty cases it was an exception for the patient to voluntarily describe this type of pain radiation and this has usually been absent even on direct questioning. In rare cases the radiation is to the right side of the chest and occasionally to the neck and lower jaw. I have seen several individuals in whom the pain was present almost entirely in the lower jaw and who, suspecting trouble in the teeth, had first consulted a dentist. When the pain is situated in the epigastrium, the patient often states that it spreads upward into the chest. It is true that radiation to the inside of the left arm, the area supplied by the first two dorsal roots, strongly indicates that the pain is of coronary disease origin, but the absence of such radiation does not in any way exclude the possibility of coronary disease.

Type of Pain.—The character of the pain is probably the most constant feature of coronary disease, certainly more constant than the site the radiation and, therefore, of greater diagnostic importance. The pain typically consists of a sense of oppression. This varies from a slight pressure behind the sternum or in the epigastrium to an intense vise-like sensation with a feeling of suffocation. Sharp, lancinating pains are extremely rare in coronary disease and very frequent in the various noncardiac types of chest pain. This was emphasized by Kilgore[8] in a comparison of chest pains in one hundred noncardiacs and thirty-six patients with pain of cardiac origin. Of the thirty-six cases of cardiac pain, the distress was described as lancinating in but four instances, and in but one case was this unassociated with pain of a compression character. Kilgore's studies also demonstrate that true cardiac pain is most frequently substernal in location, while the most frequent site in the noncardiac group is in the left chest. Chart 2, constructed from the data of Kilgore, is a graphic comparison of the type and site of pain in the cardiac and non-cardiac groups. This difference in the character of the pain frequently serves to differentiate a true coronary disease pain from various functional conditions. Our own observations agree with those of Kilgore. In only two of fifty cases of coronary disease was the pain described as of a sharp, shooting character. From a diagnostic standpoint, therefore, the presence of a compression pain is strong support for a diagnosis of coronary disease. If the pain is sharp, sticking and lancinating in character, the probability is that it is of non-cardiac origin.

Factors Inducing Attack.—In general, the factors predisposing to an attack are overexertion, emotional strain and overeating. Of these the relation to exertion is most important, for noncardiac pains are frequently induced by emotional excitement, as in the psychoneurotic, and by over-eating, as in certain gastrointestinal conditions. The importance of these predisposing factors varies in different cases. Some patients tolerate physical activity fairly well, but are very susceptible to any emotional or mental strain. Hirschfelder[9] points out that while mental excitement, anxiety, and especially anger, are frequent factors in inducing an attack, the more gentle emotions, such as pity and sorrow, even when felt intensely, have little effect.

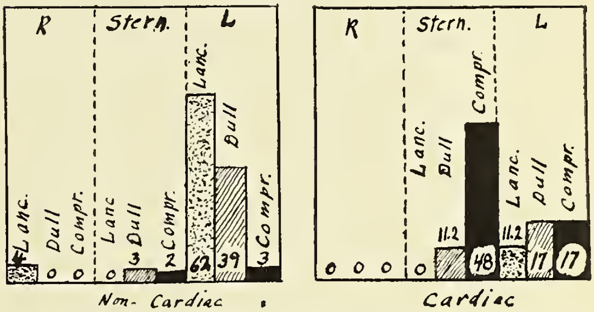

Chart 2.—Site and type of pain in non-cardiacs and cardiacs (Kilgore). Stern. indicates mid-chest; R and L indicate right and left chest; Lanc. indicates lancinating; and Compr. indicates compression type of pain.

Cessation of Attack on Rest.—The fact that effort induces a pain in the chest and rest causes it to subside is one of the more important diagnostic points. This relationship to effort and rest is usually so definite that the patient almost invariably volunteers the information without questioning. Chest pains of other sources occasionally show some relief on rest. The effect, however, is much less marked and usually this is elicited only after the patient is directly questioned concerning it.

Although the relationship of the anginal pain to effort and rest is usually definite, the attacks not infrequently occur while the patient is at rest. This occurred in five of fifty cases and in three instances the usual relationship was reversed in that the pain was relieved by moderate exertion.

Duration of Attack.—A continuous pain in the chest practically excludes coronary disease as a basis. One of the most important diagnostic features of the pain of coronary disease is the paroxysmal character, the attack usually lasting from one to five minutes. Occasionally the pain lasts for hours or several days, and then the patient presents the features characteristic of an acute occlusion of a coronary branch by a thrombus. It also is to be emphasized that one of the constant characteristics is the abrupt onset and sudden disappearance of the paroxysm. Between attacks the patient is usually in such excellent health that it is difficult for those about him to realize that he is suffering from a serious disease.

Mental Reaction.—Too much reliance cannot be placed on the presence or absence of any characteristic psychic reaction with the attack. It is true that a mental anguish with fear of impending death, so prominent in John Hunter's case, is frequently associated with the attack of anginal pain, and the presence of such a reaction is of some diagnostic value. However, many cases have repeated attacks and go on to death, suffering little or no psychic reaction with the paroxysms. Furthermore, many functional cases suffer lancinating chest pains, associated with great fear and often state that they feel as if they were about to die.

Gastrointestinal Manifestations.—The pain of coronary disease is frequently localized to the epigastrium. In the group of 113 autopsied cases the distress was referred to the upper abdomen in 25 per cent. Belching was not uncommon with an attack and the patient frequently was relieved by eructation of gas. It is often difficult to convince the patient that he is not suffering from a gastrointestinal condition. The severe prolonged pain of coronary thrombosis may suggest an acute abdominal condition. Vomiting is not rare and there may be marked tenderness and rigidity in the upper abdomen. It is frequently necessary to consider every diagnostic point to differentiate between a coronary occlusion and a surgical abdomen. The most important points in favor of coronary disease are muffled heart sounds or gallop rhythm, the presence of cyanosis, and dyspnea and characteristic electrocardiographic alterations. Dr. Arthur Zierold[10] has made a suggestion which should be helpful in differentiating an attack of pain of coronary origin from that of an acute abdominal condition. The spasm of the abdominal muscles associated with a diseased viscus is the result of a reflex, the afferent impulses passing to that portion of the spinal cord which is in segmental relationship to this viscus. The reflex is completed by efferent impulses passing from these segments of the cord to the muscles supplied by them. The afferent supply of the heart affects the somatic nerves above the sixth dorsal segment. The nerves from these segments do not supply the abdominal muscles so that a reflex spasm is not possible in a pain of cardiac origin. The muscle rigidity with the cardiac pain is merely a protective spasm resulting from cortical stimulation by the excessive pain stimulus. Dr. Zierold points out that morphine markedly depresses the cortical centers but has no such effect on the spinal reflexes. In the differentiation of a cardiac pain from a pain of a diseased abdominal viscus, morphine may be given so that the pain is relieved. A disappearance of the muscle spasm is strong evidence of a cardiac origin of the pain. If the spasm persists the evidence is in favor of a diseased abdominal organ.

Relief by Nitrites.—It is frequently of value to use amyl nitrite or tablets of nitroglycerin as a therapeutic test. Pearls of amyl nitrite or hypodermic tablets of nitroglycerin, gr. 1/150 to 1/100, are prescribed and the patient directed to inhale the amyl nitrite or place a tablet of nitroglycerin under the tongue immediately at the onset of an attack. If unmistakable relief is obtained within one or two minutes, it is almost certain that the pain is of coronary disease origin, especially if the same effect is obtained on several trials. The tablets are preferable to the amyl nitrite for this test, as occasionally a patient with functional disease responds either by way of suggestion, since the breaking of a pearl and inhalation of apparently potent drug may be impressive, or because relief is preferable to the objectionable odor of the amyl nitrite. It must also be remembered that it has been shown experimentally and roentgenologically that the nitrites act on the smooth muscle of the stomach and intestine. Abdominal pain has been controlled temporarily by nitrites when the pain was caused by spasm or hyperperistalsis of the stomach or intestine. The relief, however, is neither as immediate nor as striking as in the case of the pain of coronary disease. I have recently observed a patient who suffered attacks of upper abdominal pain. A diagnosis of coronary disease had previously been made, chiefly because the pain was relieved by amyl nitrite. However, although the duration of the attacks was shortened, relief was obtained only after a period of twenty minutes and after the inhalation of five or six pearls of amyl nitrite. Further examination revealed that the patient was suffering from cholelithiasis.

Acute Dyspnea.—The paroxysmal dyspnea of coronary disease has frequently been termed cardiac asthma, a rather unsatisfactory term, since it has no relationship to true allergic asthma and may have several underlying mechanisms. The attack consists of a paroxysm of acute orthopnea lasting a few minutes to several hours, coming on usually during sleep, but sometimes after exertion or over-eating. This varies in degree from a mild and short attack to an intense, agonizing distress which may end in death.

Any attack of nocturnal orthopnea starting in an individual above the age of forty should suggest a strong possibility of coronary disease. The diagnosis is usually not difficult. In contrast to the cardiac type, allergic asthma usually begins in young individuals and there is frequently a history of sensitization to foreign protein and of respiratory infections.

If the patient is seen in an attack, examination of the chest will reveal one of three conditions: (1) an absence of abnormal physical signs; (2) evidence of bronchial spasm as indicated by squeaky, wheezy rhonchi; or (3) many fine moist crepitations throughout the lungs. The first type is due to a disturbance in the respiratory center, resulting in Cheyne-Stokes breathing. The breathing is rhythmic during the day and the patient may be free of symptoms. The usual history is that just as he is dozing off at night, the patient is awakened by a paroxysm of labored breathing which forces him to sit up in bed gasping for breath. After a short period he falls asleep again, but may be awakened by similar attacks several times during the night. If the patient is carefully observed or if pneumographic tracings are taken, it will be found that a marked Cheyne-Stokes respiration is present and that the patient dozes off in periods of apnea and is awakened by one of the periods of hyperpnea. These attacks usually last for but a short time and are not very distressing except as they interfere with proper sleep.

The second type is more severe and prolonged. The acute orthopnea is due to a bronchial spasm. The onset is usually sudden and the dyspnea reaches the maximum very quickly. Inspiration and expiration are usually affected. The chest is filled with wheezy, musical bronchial râles such as occur in the true asthmatic.

The third type is the most severe and serious and may end in death. The orthopnea is a result of an acute edema of the lungs due to a sudden failure of the left ventricle. This usually occurs during the night but may be brought on by exertion, as straining at stool, or may follow a heavy meal. A painful oppression of the chest is followed by a spasmodic cough and usually an abundant expectoration of frothy pink sputum. The dyspnea is extreme and cyanosis is present. On auscultation many fine subcrepitant râles are heard first just at the bases and then throughout the lungs. The attack lasts from one-half to several hours and there is a disappearance of the signs in the lungs in a comparatively short time.

Physical Examination of the Heart.—It must be emphasized that an absence of diagnostic physical signs is the rule in coronary disease. The heart is usually normal in size although there may be some enlargement if hypertension is present. Even in such cases the cardiac dilatation is frequently so moderate that it will escape detection on physical or roentgenologic examination. In the cases with the short anginal attacks auscultation as a rule reveals no abnormality in the heart sounds. The rate and rhythm are usually normal. A muffling or splitting of the first sound at the apex may occasionally be present, a physical sign of doubtful diagnostic significance. In the prolonged attacks of pain associated with coronary thrombosis the heart sounds are usually very distant and muffled and the first sound may be reduplicated. Gallop rhythm and pulsus alternans are frequently present. Disturbances in rhythm of the heart are frequent in coronary thrombosis but rather unusual in coronary disease without thrombosis. In sixty cases of coronary sclerosis studied electrocardiographically by the writer, extra systoles were present in 18 per cent, auricular fibrillation in 6.6 per cent and complete heart block in 1.6 per cent.

In the evaluation of the significance of extra systoles, the time of onset is of great importance. In an individual above the age of forty, extra systoles of long standing are of little importance, while such an arrythmia of recent origin is suggestive of coronary disease. It is apparent that as compared to the subjective features, the objective examination is of a minor value in the diagnosis of coronary disease.

Electrocardiogram.—It is as an aid in the diagnosis of coronary disease that the string galvanometer undoubtedly has its greatest value to the clinician. Experimentally, it has been demonstrated that interference with the coronary circulation results in characteristic changes in the electrocardiogram. The writer,[11] from an electrocardiographic study of sixty cases of coronary disease, arrived at the following conclusions: The presence of a widened notched QRS or T wave inversion in significant leads is usually indicative of coronary disease. Other possible causes of such changes, as a large hypertension heart, aortic valvular disease with left ventricular dilatation, the post-diphtheritic and myxedema heart, may be easily differentiated and excluded. In the absence of these conditions the QRS and T wave alterations mentioned are diagnostic of coronary disease. Certain lesser deviations in the electrocardiogram such as low amplitude, minor notchings and depressed T wave, while not pathognomonic, should not be disregarded. When the clinical picture is suggestive, the presence of these lesser deviations should be considered as additional support for the diagnosis of coronary disease. An abnormal electrocardiogram is present in approximately 70 per cent of cases. Table 5 is a summary of the electrocardiographic findings in sixty cases of coronary disease.

TABLE 5.—ELECTROCARDIOGRAPHIC FINDINGS IN 60 CASES OF CORONARY SCLEROSIS

	Number	Per cent
Inversion of T	53	88
Lead I	24	40
Leads I and II	99	15
Leads II and III	17	28
Leads I, II and III	3	5
Coronary T (Pardee)	13	21
Changes in QRS		
Bundle branch block	6	10
Arborization block	2	3.3
Moderate notching	11	18
Slight notching	18	30
Low Voltage	9	15
Prolonged P-R	4	6.6
Arrhythmias		
Extra systoles	11	18
Auricular fibrillation	4	6.6
Complete heart block	1	1.6
Ventricular Preponderance		
Definite left	18	30
Slight left	18	30
Slight right	2	3.3

To summarize, the diagnosis of coronary disease depends on a proper evaluation of a number of points, especially in the patient's history. The string galvanometer when available is of great value. Although not essential for a correct diagnosis in many cases, the electrocardiogram is frequently of great value in confirming the clinical impression. There is no doubt that fewer cases would be overlooked if the frequency of coronary disease were appreciated and the condition constantly kept in mind. In a patient complaining of upper abdominal or chest pain, coronary disease must be considered, especially if the individual is a male, above the age of fifty and of the hypersthenic habitus. The presence of this condition in other members of the family and the association of diabetes or hypertension increases the probability of coronary disease. A careful analysis of each case, giving the proper value to the various points discussed, will usually enable the clinician to arrive at a correct diagnosis.

TREATMENT

There are two chief indications in the treatment of the anginal type of coronary disease: (1) treatment of the attack; and (2) the treatment directed at the underlying pathology and the prevention of attacks.

For the attack, the nitrites, first introduced by Sir Lauder Brunton in 1867[12] in the form of amyl nitrite, are still unsurpassed. Nitroglycerin was introduced by William Murrell in 1879.[13] The nitrites are effective in approximately 75 per cent of the cases of cardiac pain. In our experience the nitrites are about as effective regardless of whether the blood pressure is or is not elevated. The effect is much less certain if the manifestations are paroxysms of dyspnea although the same treatment should be tried. The inhalation of a "pearl" of amyl nitrite crushed in a handkerchief usually effects some relief in from thirty seconds to one minute. Nitroglycerin in the tablet form is preferable for several reasons. With the amyl nitrite the relief does not appear as certain as with nitroglycerin, especially in severe cases. Furthermore, the dosage of the amyl nitrite cannot be as accurately controlled, since this depends on the number and depth of the inhalations. The odor is frequently objectionable to the patient and those about him. Another point of practical importance, especially where attacks are frequent, is that the tablets of nitroglycerin are much less expensive. In bottles of 100 the tablets may be purchased at from seventy-five cents to one dollar, while the amyl nitrite is sold for about ten cents for each pearl. A freshly prepared hypodermic tablet of nitroglycerin gr. 1/100 or gr. 1/150, placed under the tongue, brings relief in from one to two minutes. It should be emphasized that hypodermic tablets be especially designated as the tablets for oral use dissolve more slowly and are thus less effective. When taken by stomach the drug is about one-half as effective and relief usually does not appear for about ten minutes. A frequently mentioned objection to the use of the tablets is that the drug may deteriorate in this form and thus become comparatively inert. Although this possibility theoretically exists, in practice the hypodermic tablets with the modern methods of preparation retain their potency for long periods. An unsatisfactory therapeutic effect may be due to faulty tablets, a wrong mode of administration or inadequate dosage. The physician should first proceed to examine the tablets to determine whether they are in the hypodermic form and dissolve quickly and whether they appear fresh or old, hard or discolored. He may find that the patient is taking the tablet by stomach instead of by the sublingual route. If these points are corrected and the effect is still unsatisfactory, an increase of the dosage should be tried. Ingalls and Meeker[14] emphasize the fact that large doses are often needed and when ordinary doses are ineffective the patient may obtain relief by increasing the number of tablets. Osler also states that nitroglycerin is too timidly used and then abandoned as ineffective. If the physician increases the dose gradually, no harm can come, with the exception of some headache. The patient should be warned of possible dizziness and headache, and assured that this reaction is harmless. It is frequently wise for the physician to test the tolerance of the patient in the office to determine the degree of dizziness, palpitation and headache with a certain dosage. Nitroglycerin may also be used in the form of the spirit of nitroglycerin, also known as spirit of glonoin, spirit of glyceryl trinitrate or liquor trinitri. One or two drops of this preparation placed under the tongue has the same effect as the tablet. In the use of the liquid form, the U. S. Pharmacopeia advises pouring a solution of potassium hydroxide if any is accidentally spilled, otherwise after evaporation of the alcohol, a highly explosive substance remains. The tablets are more convenient to carry and to apply. The patient must be instructed to have the drug close at hand at all times and to administer it immediately at the onset of the attack. A drink of whiskey or brandy will check the attack of pain in many cases. This was noted by Heberden in his original description in which he stated that "wine and spiritous liquors afford considerable relief."

In the prolonged and severe attacks of pain with fall of blood pressure, resulting from a thrombosis of a coronary branch, the pain is seldom relieved by nitrites and their administration may be harmful. An additional drop in the arterial pressure may occur, intensifying the degree of shock. The pain can be relieved only by morphine and the dose should usually be no less than one-half grain, which should be repeated if necessary. Smaller doses are usually ineffective in this condition.

If the attack consists of a paroxysm of dyspnea, the nitrites should be tried, but frequently are ineffective. Palmer and White,[15] in a review of a series of cases of cardiac asthma, found that nitrites gave some relief thirty-seven times, and no relief twenty-eight times. The relief is much less striking than in the cases of cardiac pain. Morphine is the most reliable remedy, regardless of whether the shortness of breath is due to edema of the lungs or bronchial spasm. If auscultation of the lungs indicates that bronchial spasm is present, adrenalin or ephedrin may be used. These drugs seem to be as effective in the attacks of bronchial spasm associated with coronary disease as in the true allergic asthma. In cases having frequent attacks, ephedrin in .050 gr. doses two or three times a day has been successful in preventing attacks. I have seen many patients in whom one capsule of ephedrin at bedtime has prevented nocturnal attacks of bronchial spasm which previously had been relieved only by a hypodermic of morphine. Bloedorn and Dickens[16] from observations on a single case conclude that ephedrin is a dangerous drug in cases showing evidence of cardiac damage, stating that it may produce acute cardiac decompensation and pulsus alternans in patients with damaged hearts. I have observed no harmful effects from the use of ephedrin in cardiacs, unless the drug was continued in a patient showing an untoward reaction, such as tachycardia, tremor, nervousness and weakness. Many of the cases of nocturnal paroxysmal dyspnea of coronary disease are associated with Cheyne-Stokes respiration, the patient awakening in the phase of hyperpnea. This abnormal type of respiration may frequently be successfully treated by the use of an ampoule of euphyllin, 0.5 gm., administered either intramuscularly or intravenously. In addition to the use of morphine, venesection is usually recommended in cases showing edema of the lungs. I have been impressed with the frequency of a shock-like condition associated with the edema of the lungs of coronary disease. The venous pressure as evidenced by collapse of the jugular veins is low, due to a peripheral circulatory failure with active dilatation of the splanchnic vessels. In such cases venesection is certainly not indicated and the procedure should be attempted only where there is evidence of increased venous pressure as indicated by distended jugular veins. Obrastzow and Strashesko[17] mention a case in which they opened the cubital vein and the venous pressure was so low that no blood was obtained.

The treatment for the purpose of preventing attacks may be divided into: (1) certain general measures to readjust the patient's activities and habits; (2) drug therapy; and (3) surgery.

General Therapeutic Measures.—The most important feature in therapy is the rearrangement of the individual's activities and habits. A life free from mental and physical strain must be ordered. Too often the physician dismisses this most important feature in therapy with the brief instruction to the patient to "take things easy." This is insufficient, for it is important to make a careful study of the activities and mental and physical habits of each patient and the factors inducing the attack. It is difficult to formulate any general rules of management as each case must be considered individually. A balance must be arranged between too much and too little restriction. Some patients require extreme limitation, others are benefited by moderate exercise. It is very seldom that complete bed rest is necessary. However, if the attacks are persistent in spite of definite restriction, rest in bed for a short period with a gradual increase in activities should be tried. It is seldom also that the patient is required to give up his business or profession. Each patient's work and his physical and mental reaction to that work must be studied. A reduction in the time and the amount of work, elimination of the factors tending to mental and emotional strain and reasonably frequent periods away from work will usually permit the patient to carry on much of his usual activity.

It is very important that a proper state of mind is established. It is necessary to impress the patient sufficiently so that he will follow instructions and yet to reassure him so that he does not become unduly apprehensive. It is surely not a successful therapeutic result to obtain a restriction of physical activities at the cost of additional mental strain. In addition the patient should be familiar with the causes which are most liable to induce an attack, such as sudden, prolonged and strenuous exertion, emotional excitement, overeating, especially if followed by some exertion, excessive use of tobacco, constipation and straining at stool. He will then be able to make an effort to avoid these predisposing factors.

A degree of physical exercise, and this varies in individuals, is not harmful and may be beneficial. The degree of exertion must always be below the pain producing level. Walking is the best form of exercise. This is well tolerated with few exceptions, if it is not done immediately after meals, in the face of a wind, or in extremes of weather. Many patients may indulge moderately in golf, especially if on a fairly level course.

Restriction in diet is important. This consists chiefly in ordering meals small in amount to prevent overloading and distension of the stomach. If the patient is overweight this will also have a favorable effect in reducing the weight. Small lunches between meals may be added if necessary. Seasoned, irritating and fried foods and those containing much roughage should be eliminated to prevent flatulence. A short rest after each meal is necessary and no exertion should be attempted for at least one-half hour. Tea and coffee may be used in moderate amounts. To eliminate coffee in an individual who is accustomed to its use is inconsistent when one considers that caffein is tri-methyl xanthin and the chief coronary dilating drugs usually administered are also xanthin derivatives. Alcohol in small amounts may be well tolerated, but overindulgence is distinctly harmful.

In all cases it is of importance to regulate the use of tobacco and in many individuals it is advisable to exclude it completely. With many patients accustomed to the use of tobacco, the smoking of part of a cigar or a cigarette after a meal promotes the desired relaxation and rest. Restriction in these cases is more beneficial than complete exclusion of tobacco. There are no conclusive clinical or experimental observations which support the theory that tobacco will cause or increase the tendency to arteriosclerosis. Albutt[18] concluded that the effect of tobacco in hyperpiesia and arteriosclerosis was negligible. Johnson[19] found in sixty patients suffering with angina pectoris that 70 per cent were smokers and 30 per cent non-smokers. Of a control group of 1,000 adult males, 81.8 per cent were smokers. His conclusion was that tobacco was a very doubtful etiological factor. Arteriosclerosis has been noted in rabbits after the injection of nicotine. These observations have been poorly controlled and conclusions from these experiments are unreliable. There is evidence, however, that tobacco may cause acute constriction of the blood vessels, and it has been noted that excessive use of tobacco may induce anginal attacks. Moschcowitz[20] reports in a group of cases a striking cessation of typical anginal attacks in heavy smokers when tobacco was withdrawn. There is no doubt that most individuals with diseased coronary vessels will be less susceptible to attacks if tobacco is definitely restricted or excluded.

Use of Coronary Dilators.—The chief drugs for this purpose are the xanthin derivatives. Caffein is trimethylxanthin, theobromin is dimethylxanthin, its isomer theophyllin is usually known the trade name of theocin. There are many compounds of these drugs, the one which has been for the longest time in general use being theobromin sodium salicylate, known as diuretin. As early as 1895 Askanazy[21] called attention to the effectiveness of this drug in anginal manifestations. In 1902 Breuer[22] confirmed the observations of Askanazy and stated on the basis of five years' experience "that he considered the use of theobromin in cardiac asthma and angina pectoris as one of the most praiseworthy therapeutic attainments of the last ten years." More recently there has become available the calcium salt of theobromin and salicylic acid known as theocalcin and a compound of theophyllin, theophyllin ethylenediamin, known by the trade name of euphyllin or metaphyllin. Experimentally it has been shown that these drugs definitely dilate the coronary arteries, increasing the flow through these vessels in doses comparable to that which can be administered therapeutically. Smith, Miller and Graber[23] show that euphyllin increases the rate of coronary flow from 40 to 90 per cent and that this gain is independent of the accelerated heart action. They state that the action of this drug compares favorably with that of glyceryl trinitrate but that the effect is much more prolonged. Caffein sodio-benzoate and theobromin sodio-salicylate have no such favorable effect on the coronary circulation. Theophyllin increased the flow from 25 to 40 per cent.

The work of Gilbert and Fenn[24] indicates that in point of efficacy the drugs assume the following order: theobromin and its derivatives, most effective; euphyllin, theophyllin sodium acetate and caffein have the least effect on the coronary circulation. Musser[25] found euphyllin very effective in the treatment of cardiac pain and paroxysmal dyspnea. Gilbert and Kerr[26] used the various compounds of theobromin and theophyllin in eighty-six cases of anginal pain. They considered that theobromin and its compounds were somewhat more effective but found that certain cases responded to euphyllin which did not respond to theobromin or its compounds. Many of the xanthin derivatives have untoward effects which limit their use. These consist of nausea, occasional emesis, burning in the epigastrium, palpitation and dizziness. With the exception of theobromin, theocalcin and euphyllin, these preparations can be used only by a few patients for more than a few days without ill effects. Our own procedure has been to use theocalcin and euphyllin alternately. Theocalcin is supplied in 7.5 grain (0.5 gm.) tablets and four to eight tablets are prescribed a day. This drug has been administered to many cases for long periods without gastric irritation and with beneficial effects in preventing anginal attacks. Euphyllin or metaphyllin is supplied in 1.5 grain (0.1 gm.) tablets and dosage varies from four to ten tablets a day. The patient is advised to use one of the preparations for from ten days to two weeks and then to shift to the other drug for the same period. Theominal, a preparation consisting of theobromin, 5 gr., and luminal, 0.5 gr., is valuable where a sedative is needed and may be used in conjunction with or alternating with euphyllin. Erythrol tetranitrate, gr. 0.5, three times daily, has been used in a small group of cases in which hypertension was present with apparently favorable results.

Surgical Measures.—In recent years much attention has been given to the surgical treatment of the anginal pain. The aim of the various methods which have been used is the interruption of the afferent nerve fibers which convey the impulses arising in the heart. The most important routes of sensory impulses from the heart are by way of the upper, middle and lower cardiac nerves to the cervical sympathetic trunk and also by way of a large number of fibers coming into the stellate ganglion. There are also lower fibers which enter the dorsal sympathetic chain. The impulses then pass from the cervico-dorsal sympathetic chain to the spinal cord by way of the rami communicantes of the upper dorsal nerves. The literature is replete with descriptions of a variety of methods for the interruption of these sensory routes. The chief point of attack has been the cervical sympathetic chain. Jonnesco[27] in 1916 first removed the upper three cervical ganglia and the first dorsal sympathetic ganglion on both sides. With this elaborate procedure he reported good results. Various less radical operations on the cervical sympathetic chain have been suggested. In 1923 Coffey and Brown[28] removed the superior cervical ganglion in five cases with relief of pain, a comparatively simple procedure. This method has been used extensively. It has been demonstrated that there are no sensory fibers in the superior cervical ganglia and there is therefore no blocking of sensory impulses by this operation. This ganglion has a purely motor function and any favorable effects following its extirpation can only be explained by a coronary vaso-dilatation resulting from a suppression of vaso-constrictor impulses. Wenckebach[29] has proposed that the sensory impulses from the heart are carried by the depressor nerve. Eppinger and Hofer[30] tried cutting the depressor nerve, and report a certain amount of relief. Cutler,[31] who in this country has had considerable experience with the various methods, states that it is doubtful whether this nerve can be identified in an operative procedure. Cutler has reviewed 120 cases subjected to various types of operation. The best results were obtained by the radical operation of Jonnesco, interrupting both sensory and motor fibers with relief in 62.9 per cent and improvement in 18.5 per cent. Simple extirpation of the superior cervical ganglion resulted in relief in 34.4 per cent and improvement in 38 per cent.

Surgery upon the cervical sympathetic chain is usually followed by certain disagreeable after-effects. This includes enophthalmos, myosis, ptosis of the lid, and absence of flushing or sweating on the operated side. (Horner's syndrome). Also sensory disturbances may follow for a variable period, such as burning sensations and hyperesthesia of the face, neck and upper chest.

More recently the blocking of the pain impulses from the heart has been attempted by a less radical procedure, the injection of the dorsal root ganglia. This was first carried out by Mandl,[32] who injected novocaine paravertebrally with excellent results in sixteen cases. Swetlow[33] in this country has published several reports and describes his technic in detail. He uses 85 per cent alcohol, injecting paravertebrally the upper five to eight dorsal ganglia with much success in the relief of the precordial pain. In most cases there is some benefit, and in many the pain entirely disappears. This method requires some experience in nerve injection and a knowledge of the anatomy. An improper injection yields no benefit and may injure the pleura, or spinal cord, causing a serious reaction. Certain disagreeable after-effects may follow the paravertebral injection procedure, usually lasting but a few days, but occasionally for weeks. These consist of burning sensations, paresthesias, and hyperesthesia of various parts of the chest. Richardson and White[34] compared the results of cervical sympathectomy with those of paravertebral alcohol injections and conclude that the injection method is superior. Since the injections were first attempted by these observers, the results have been so favorable that the operative methods have been discontinued.

It must be emphasized that these methods of treatment are purely symptomatic. There is no attempt to cure or relieve the underlying pathology unless it be the questionable vaso-dilatation of the coronary arteries which may follow the extirpation of the motor fibers in the superior cervical ganglion. It is clear from a review of the reported cases that life is not prolonged and that the tendency to sudden death is not avoided. It certainly may be argued that suppressing the pain removes a warning signal, a valuable indication to the patient that the heart has been overburdened. Mackenzie[35] strenuously criticizes the surgical treatment for this reason. He points out that many patients learn to recognize the significance of the pain and the circumstances that provoke it and by avoiding these circumstances can often lead useful lives free from distress for many years. This justifiable criticism deserves serious consideration. It must be remembered that the trouble does not lie in the pain, but in the underlying pathological condition. The surgical and injection methods should be reserved only as a last therapeutic resort to patients suffering from intense, incapacitating anginal pain which does not yield to simple measures. Such cases occasionally are encountered and the injection in capable hands is distinctly indicated. The writer, in an analysis of fifty-five patients with anginal pain, found but one case that appeared suitable for this type of treatment. It is clear that the radical measures are rarely necessary, as most patients remain reasonably comfortable, employing the simpler methods of treatment.

Radiation therapy is frequently mentioned as a treatment, especially in the French literature. Thus far the duration of observation of the treated cases has been insufficient to justify any conclusions as to the value of this method. The basis of this method is that the posterior ganglia might be influenced by radiation much the same as by the injection of alcohol. Sussman[36] in this country demonstrated in animals vacuolization of the cells and edema in the sympathetic ganglia after irradiation. He reports favorable results in sixteen cases but states that the period of observation has not been sufficiently long to warrant definite conclusions.

Diathermia has also been attempted on the theory that an increased temperature might induce dilatation of the coronary system. Brown, Alt and Levine[37] in animal experiments concluded that appreciable changes within the chest could be obtained only when such intense diathermic currents were employed that serious burns and sloughing of the tissues were likely to occur.

SUMMARY

1. There are two distinct clinical pictures associated with coronary disease: (1) the anginal syndrome consisting of attacks of pain or acute dyspnea; and (2) the manifestations of congestive heart failure.

2. Coronary disease with congestive heart failure is usually associated with hypertension and presents practically the same problems in diagnosis and treatment as congestive failure from other causes.

3. The diagnosis of the anginal type is frequently very difficult as the clinical picture may be atypical and variable.

4. The diagnostic features of the anginal type are enumerated and discussed and an evaluation made of the various diagnostic criteria.

5. Significant physical signs are usually absent.

6. The electrocardiogram is of great aid in diagnosis, and shows some abnormality in about 70 per cent of the cases.

7. There are two chief indications in treatment: (1) the treatment of the attack; and (2) therapy directed toward the underlying pathology and the prevention of attacks.

8. The anginal pain is most favorably treated by the sublingual administration of hypodermic tablets of nitroglycerin in sufficient dosage. The disadvantages of other nitrites are discussed.

9. Paroxysmal dyspnea reacts less favorably to nitroglycerin and usually requires morphine. Many cases respond satisfactorily to ephedrin.

10. The therapy aiming at the prevention of attacks includes: (1) the readjustment of the patient's activities and habits; (2) the use of coronary dilating drugs; and (3) surgical methods for interrupting the sensory impulses from the heart. These therapeutic methods are discussed in detail.

THE REMOTE EFFECTS OF HEAD INJURY*

W. H. Hengstler, M.D.
Saint Paul

IN A recent article, "The Neurological Aspect of Head Injury," published in Minnesota Medicine for June, 1931, we discussed, in a general way, the neurological phases of head injury, especially those which manifest themselves at the time of injury and immediately afterward. It is now our desire to proceed further and discuss the remote effects of head injury, from the neurological standpoint, particularly those effects which may appear to be permanent and which from a compensable point of view have such an important bearing upon the opinion which the physician is to give in Court or before the Industrial Commission. With the ever-increasing number of head injuries, industrial and otherwise, it is important for every medical man to be familiar with the accepted status of the various disabilities which are claimed as a result of head injuries. The purpose of this presentation is to review the various remote effects of head injury, and to present briefly their "present-day" status. By remote effects we mean those which persist for a period of longer than three months after the injury, or which make their initial appearance more than three months after the injury is received.

First of all it is proper to enumerate all of the possible remote effects which may be concerned with the disability of the injured individual, and with respect to which the questions of permanency and disability may arise. They are as follows: (1) mental impairment or mental derangement; (2) epilepsy; (3) cranial nerve injuries; (4) paralyses; (5) functional nervous disorders of various kinds.

Each of these occupies its own place in relation to head injury, and the most intelligent discussion can be arranged, therefore, by taking them up one at a time.

Mental Impairment or Mental Derangement.—Insanity following head injury and due exclusively to the injury itself is comparatively rare, even in cases where there has been severe skull and brain injury. While the so-called "traumatic psychosis" is a definite entity, its existence means that there must be structural injury to the brain, either by laceration, contusion or hemorrhage, or by depressed skull fracture. It implies, also, a certain sequence of symptoms and cannot be accepted as a diagnosis if there is a long interval between the time of injury and the onset of the mental symptoms. Adolph Meyer, in 1904, presented the original conception of traumatic insanity, and, peculiarly enough, his original conception has remained almost unchanged up to the present time. The typical case of insanity, due solely to head injury, must conform to the following sequence of events: A severe head or brain injury followed by unconsciousness or delirium, recovery later with grave defect symptoms, with marked changes in behavior, with sullenness, irritability, increased susceptibility to alcohol, dizziness or vertigo, and a psychosis which usually becomes progressively worse. There must be direct continuity in its development, with no intervening period during which the individual is normal. This is the only situation in which insanity may be correctly attributed to head injury alone. Mental derangement may follow head injuries and even injuries to other parts of the body, but in the absence of structural damage to the brain or in non-cranial injuries, the trauma cannot be construed as the entire cause of the insanity. It must be viewed as a contributing factor in a predisposed individual. Here, again, there must be direct continuity established between the time of the injury and the onset of mental symptoms. It is well recognized, at the present time, that if insanity is to be attributed to trauma, either as a sole cause or as a contributing factor, there must be shown direct continuity and sequence of symptoms from the time the injury is received up to the time the mental symptoms first appear, and that if there is a period of more than thirty to ninety days after the injury, with no mental symptoms, then it is extremely unlikely that the injury is a causative factor.

Head trauma may supply the emotional factor which precipitates a manic-depressive psychosis in a person predisposed to it. Likewise, it may be a contributing factor in lighting up a dementia precox, which was present, but latent, before the injury. However, neither of these must be confused with traumatic insanity. Here, again, must be established direct continuity and sequence between the injury and onset of symptoms, with no appreciable period of normal recovery between the two. It is definitely recognized that head injury plays a part in the development of dementia paralytica, presumably by increasing the permeability of the cerebral vessels to the spirochete and the luetic virus, thereby causing a latent syphilis to become active and cerebrally localized. Here, as in other insanities, the time relationship is most important, and each case must be evaluated through study of the history of the mental condition prior to the injury, and the length of time, after injury, before mental symptoms appeared.

---

*Presented before the Northern Minnesota Medical Association at Hibbing, Minnesota, September 14, 1931.

In dementia paralytica, if mental symptoms appear immediately following head trauma, then no just claim of causation can be made for the injury, because the organic and structural changes of dementia paralytica cannot develop rapidly. An interval at least of several months is necessary for these to occur, subsequent to the injury, and yet this interval must not be too long. There is difference of opinion as to the length of this period, but its limits are accepted, usually, as from six months to two years. In other words, if the symptoms of dementia paralytica appear within six months following the injury, or later than twenty-four months after the injury, then the injury itself is not a causative factor in the development of the disease.

In all cases of insanity, supposedly caused by injury, one must obtain, from reliable sources, a most careful background of family and personal history, development of personality, and presence of peculiar characteristics in the individual during his lifetime prior to the injury. Honest and well-meaning persons will often make very definite statements that the individual was perfectly well prior to the injury, when as a matter of fact he was actually psychotic or nearly so. It is a persistent and erroneous belief among people that insanity is often caused by a blow on the head, even years before the onset of the psychosis, and they invariably try to connect some trivial bump on the head with the evolution of a mental disorder. Actually, however, statistics prove that only a fractional part of one per cent of insanity cases in institutions is associated with trauma as a causative factor.

Mental deficiency or feeble-mindedness, following head injury, is almost unknown. It cannot occur unless there has been severe structural brain injury. It is very common for feeble-mindedness to be claimed in children who have had head injuries of one kind or another, but careful checking up of the child's history, before the injury, will usually prove that if feeble-mindedness is present it was congenital. Any claim of parents or attorneys that a child who has sustained a head injury is feeble-minded as a result of it, should instantly rouse suspicion in the mind of the physician, and he should investigate very carefully before expressing his opinion.

Epilepsy.—In the case of epilepsy following head injury, as with insanity, the medical man must use extreme care in arriving at a conclusion, for here, again, the public is prone to furnish information which is not fact. In the first place, very few head injuries result in epilepsy. A most careful history of the individual and his family should be obtained, and in the greater percentage of cases, especially in those where there has been no structural brain injury or skull fracture, it will be proven that if epilepsy really exists, it was there before the injury. This is especially true in epilepsy of the idiopathic form. If the Jacksonian type of seizures occur, that is evidence of focal brain irritation and is much more likely to be traumatic in origin. Frequently, in severe head injury, epileptiform spells will occur soon after the injury—possibly in a few moments or a few hours. In these cases, it is usually due to sudden brain irritation, caused by edema or hemorrhage, and disappears promptly with the subsiding of the edema or absorption of the hemorrhage. If due to depressed skull fracture, operative interference will relieve the attacks. These spells occurring soon after injury cause less anxiety than those appearing some months later, due to scar formation, cysts or other secondary changes in brain structure. It must be borne in mind that the emotional reaction from an head injury may light up an old epilepsy which had been quiescent for a long time. If this occurs, it must be conceded that the injury was contributory in cause, as it aggravated a preëxisting condition. It is difficult to give an accurate "elimination period" for epilepsy which follows head injury. It is, however, generally conceded, that if spells begin later than one year after the injury, the epilepsy is not due to trauma, unless some focal brain injury can be demonstrated.

In the *London Lancet,* for October 27, 1928, W. W. Wagstaffe, writing on "The Incidence of Traumatic Epilepsy after Gunshot Wound of the Head," arrives at the following interesting conclusions, after analysis of three hundred and forty post-war patients who were still alive:

1. Traumatic epilepsy is nearly ten times more common in penetrating wounds of the dura than in other head injuries.
2. The site of the wound has no influence on the onset of traumatic epilepsy.
3. Traumatic epilepsy is more than twice as common in cases of penetrating wounds of the dura which show severe organic lesions, than in those which do not.
4. Traumatic epilepsy may come on at almost any time after a gunshot wound of the head. (In his series the variation was from two months to seven and one-half years.)
5. Traumatic epilepsy appears to be much more common in those patients who show transient Jacksonian fits within a few days of the injury.
6. Traumatic epilepsy is somewhat more common where a metallic fragment has remained in the brain.
7. The mortality in those who develop traumatic epilepsy is rather higher than in other cases of gunshot wounds of the head.

In the same article, he quotes P. Sargent as finding four and one-half per cent of epileptics in an analysis of eighteen thousand cases of gunshot wounds of the head.

Cranial Nerve Injuries.—In cranial nerve injuries following head trauma, the nerves most commonly affected are the first, third, sixth, seventh and eighth. These injuries manifest themselves in the so-called cranial nerve palsies, and produce paralyses or derangement of function in the organs supplied by the nerves. Loss of sense of smell, interference with the motor-oculi group, facial paralysis, and impairment or loss of sense of hearing are very common, particularly following basal skull fracture. There can be no mistake in diagnosis in cases where cranial nerve palsies are concerned, for they are always clear-cut and well-defined, and occur reasonably soon after the injury is sustained—usually within forty-eight to seventy-two hours.

Paralyses.—Paralysis which follows head injury may be organic or functional in causation. If organic, it is the result of structural brain injury, either as a result of laceration, contusion, hemorrhage or depressed skull fracture. The paralysis appears in that portion of the body whose motor control lies in the injured brain area. We may have hemiplegia or monoplegia, complete or incomplete, with or without facial involvement, and with or without sensory involvement, depending upon the location and extent of the brain injury. Paralysis may be temporary or permanent, depending, also, upon the degree of brain injury. If functional, the paralysis is that which is ordinarily considered hysterical, and is the result of psychic trauma, and not physical or structural injury. Here, again, we may have partial or complete paralysis involving one or more groups of muscles, but in this type of paralysis the degree of disability does not depend upon the severity of the injury. Psychic trauma may occur as the result of a very slight injury, where the power of suggestion is strong enough to produce in the individual the conversion of an idea into a physical manifestation. Such paralysis is very common, particularly in cases where compensation or litigation is involved.

Functional nervous disorders of various kinds.—Functional nervous disorders following head injury presents, by far, the biggest problem to the physician who concerns himself with examination and evaluation of head injuries. Here we have an intricate mass of subjective symptoms not substantiated by objective findings. There are so many types of disorders in this group that it is not possible to discuss them singly at this time. These are the patients who have reacted emotionally to injuries which in themselves are often very trivial and which are not concerned in any way with evidences of organic injury to the brain or central nervous system. The emotional side is so disordered that fear and horror are aroused and prolonged long after the injury itself has ceased to have a prominent place in consciousness. Here we have the normal personality replaced, at least to some extent, by intricate abnormal psychological patterns, and there is more or less suppression of normal self-confidence and normal will power. Fear and anxiety are frequently powerful enough to produce actual constitutional changes in the individual. He lives over and over again the experiences of his injury, and his resultant emotional reactions are often associated with and augmented by those mal-adaptations of his ordinary life, which had never before been oppressive, but which now appear to be tremendously exaggerated. In persons who have an adequate and well-balanced personality, these reactions, if aroused, do not last for any great length of itme. They do, however, in many cases, result in so much anxiety that a change of occupation or of occupational environment is necessary to bring about a return of normal adjustment.

Head injury carries with it powerful suggestion of fear, and following such injury we are apt to have a more severe actual neurosis than that which occurs after injury to any other portion of the body. The true traumatic neurosis may constitute a very real disability, and must not be confused with the compensation or litigation neurosis, or malingering. Traumatic neuroses may vary greatly in their symptoms and severity. They are characterized and engendered by fear and anxiety, which centers upon the individual himself, concerning both his present condition and his future welfare. In the compensation or litigation neurosis, anxiety is directed particularly toward the question of how much is to be paid for the injury, or fear over having to appear in court. In the malingerer, there is willful pretense, for purposes of securing financial gain. Upon the physician falls the burden of distinguishing between these three conditions, and of determining the amount and duration of disability. In judging such individuals, there are important things to be considered. Ability to sleep, condition of body weight, ability to concentrate mentally, and general emotional stability are very important, but most important is the study of the individual himself, and the analysis of his attitude, of his motive, and of his sincerity. The true traumatic neurosis presents often very frank constitutional symptoms. The litigation neurosis and the malingerer never show these. This mammoth group of cases deserves attention, which, for lack of time, cannot be given in this presentation. They constitute the greatest problem in industrial medicine today, both to carriers of insurance, to employers and to medical men.

In conclusion, a brief discussion of permanency in remote effects of head injury is pertinent. Actual traumatic insanity is, in most cases, permanent. Arising as it does from structural brain injury, there is small chance of a return of normal mental capacity. The same may be said of mental deficiency or mental impairment arising as a result of brain injury. If the space of one year passes with no improvement in the psychosis, it can be said to be permanent. The same is true of manic-depressive insanity or dementia precox, in which the trauma has played a causative part. The prognosis in manic-depressive insanity or dementia precox, caused partially by the emotional reaction of head injury, is just the same as it would be in manic-depressive insanity or dementia precox which develops spontaneously and without head injury. In the former, sixty to seventy per cent recover; in the latter, a twenty to thirty per cent recovery may be expected. If, however, the psychosis is prolonged for one year following the injury which was concerned in its production, then one may reasonably expect permanency.

In epilepsy which arises after head injury, assuming that it is due to the head injury, we may expect permanency if the spells continue from twelve to eighteen months after the injury is received. Within that period, there is a reasonable possibility of recovery from the structural injury causing the spells and cessation of the spells.

Cranial nerve palsies and peripheral paralyses persisting for more than six months after the injury are in all probability permanent. The average cranial nerve palsy or peripheral paralysis of organic causation, which is going to recover, will do so within two to six months after the injury is received. Suspicion of permanency is justifiable after six months, and certainty of permanency is justifiable after one year has elapsed.

In the functional group of cases following head injury, we rarely find permanency. In all these cases, settlement of claims for damages and clearing up of litigation is very important, and should always be advised at the earliest possible moment. In the true traumatic neurosis, recovery will not occur as rapidly as in the compensation or litigation type. In the ordinary head trauma, where there has been no skull fracture or organic brain injury, one may expect a reasonably rapid recovery after questions of litigation and compensation have been settled. Three months' time is usually sufficient for an individual to return to duty, in this type of case. In the simple skull fracture, without depression of fragments or brain injury, from three to six months is usually required for the individual to readjust himself. In cases where a severe traumatic neurosis arises, which is characterized by substantial loss in weight, profound insomnia, definite depression, and inability to concentrate mentally, we may have disability ranging up to eighteen months following the injury. It would be most unusual for such cases to be permanent.

In head trauma, where there has been skull fracture, with displacement of fragments, and where there has been contusion, laceration, or hemorrhage, affecting the brain or its coverings, we may have all degrees of disability, ranging from partial and incomplete disability for a number of months, with recovery, to complete and permanent disability—the result of organic changes in the brain. It is in cases of this type that particular skill is required in summing up the individual's condition and arriving at an accurate conclusion as to what may be expected in his future.

One difficulty very frequently encountered by the physician, in his attempt to rehabilitate the functional nervous case following head trauma, is the impossibility of securing some light form of work for the patient. Many cases, receiving comparatively minor head injury, are so overcome with fear as a result of the circumstances which surrounded their injury, that for a time they are unable to command themselves sufficiently well to return to their normal occupation. This is true, particularly, in individuals who work in high places, such as structural steel workers. In these cases, rehabilitation may often be accomplished if the individual can be given some light form of work, where he can reëducate himself and set aside the fear which has possessed him. It is very difficult to secure coöperation from employers, who cannot understand why a man who looks physically strong should be unable to resume his former occupation in the air.

Time does not permit further discussion of this intensely interesting subject, which is so pertinent to physician, insurer and employer today. It behooves every medical man who is concerned in this type of practice to give attention and study to this group of cases, in order that justice be meted out to all concerned.

1068 LOWRY MEDICAL ARTS BUILDING.

TUBERCULOSIS IN A RURAL COMMUNITY*

Edwin J. Simons, M.D.
Swanville, Minnesota

THERE are 1,400 organizations throughout the United States, the primary object of which is the eradication of tuberculous disease. The mortality rate of tuberculosis has decreased from 202 per 100,000 population in 1900 to 97 per 100,000 in 1922. This achievement has been possible only through the constant energetic work of these anti-tuberculosis societies and of individuals primarily interested in the disease. Thus far, their efforts have been concentrated upon cities and their environs. Rural communities have received some attention; yet the interest and active coöperation of country practitioners have not been enlisted fully.

Perhaps the greatest good that a paper such as this might accomplish is to demonstrate that any country community presents a fruitful field in which to continue the campaign against tuberculosis. If this is shown, and if thereby the interest and coöperation of rural practitioners are aroused, then a course of procedure available to the country doctor for the diagnosis of early as well as advanced cases of pulmonary tuberculosis must be outlined. It is hoped that the narration of events experienced in the attempted control of the disease in the farm region centering around the village of Swanville, Morrison County, may help to accomplish either or both of these ends.

During the summer and fall of 1929, first whooping cough and then measles reached the proportions of mild epidemics. Both of these diseases predispose to tuberculous infection, and their occurrence gave a warning that an increased incidence of tuberculosis might be expected. In December, a high school girl died of tuberculous meningitis. Several months later a high school graduate of the previous year was found to have moderately advanced pulmonary tuberculosis. In June, 1930, a three year old girl died of tuberculous meningitis; and shortly after her death a third high school girl was found afflicted with a pulmonary lesion.

Three of these patients had had either measles or pertussis during the year preceding the diagnosis of tuberculosis. Two of the three high school students had had productive coughs, and tubercle bacilli were demonstrated in their sputa. Two of them lived on farms from which cream was sent to the local creamery. Two delivered milk to customers of the village milk route.

These facts definitely indicated a greater incidence of the disease than had previously been suspected and suggested rigorous vigilance for the detection of other cases. It appeared necessary, immediately, first, to arrange a course of procedure for the certain detection of new cases, and, second, to adopt an epidemiological approach to the problem from every possible angle.

The definite routine set up to detect new cases is adjustable to any rural practice and is thorough enough to avoid failure of recognition of the disease, whatever the type or mode of onset. A detailed history is taken and a careful physical examination performed. When these two procedures arouse suspicion, the patient is asked to keep a daily temperature record with readings recorded every four hours, and is taught how to do it. Any rise above 99° F. in a male patient or 99.6° F. in a female one, or any variation of more than 1.5 degrees during the day, is considered, if persistent, corroborative evidence. Repeated sputum examinations are made. The von Pirquet tuberculin test is used as a routine, but where it leaves any doubt the Mantoux test is applied. All atypical childhood or adult cases of pneumonia are subjected to tuberculin tests. Whenever these tests show a positive reaction, X-ray plates of the chest are taken and are submitted to some recognized roentgenologist for interpretation. Basal metabolism tests are made and repeated as necessary. Tuberculosis is diagnosed only after the postulates of the National Tuberculosis Association are fulfilled. Each diagnosis made is confirmed by consultation.

Besides proving the diagnosis in the four cases already cited, this schedule led to the discovery of seven other cases: two of far-advanced adult apical lesions, one moderately advanced adult case, two basilar lesions (one with an acute and one with an insidious onset), one early infiltrative lesion in an adult, and one infiltrative lesion with an acute onset in a four-year-old child. Two of these cases presented some obscurity and diagnostic difficulty, and the diagnosis was not considered definitely established until confirmed by consultation.

---

*Presented before the Mississippi Valley Conference on Tuberculosis, St. Paul, September 21, 22 and 23, 1931.

These diagnostic procedures provided adequately for the discovery of new cases in practice, but the epidemiological features of the disease became more prominent with each new case. Partial postmortem examination in the first case mentioned revealed a far advanced lesion in the left upper lobe. There were six other children in this family, and the father and mother had been in poor health for months. The whole family had lived for years on a farm, and three years prior to their moving into the village one cow of their dairy herd had died of tuberculosis. Later, three other cows in this herd were found to be infected. Two of the children had had measles and two had had pertussis within six months of the death of their oldest sister. Also, it was known that the girl assisted in the delivery of the village milk supply.

The father was sent to the University Hospital, where it was determined that he was suffering from incipient bilateral tuberculosis. Von Pirquet tests, roentgenograms and continued observation demonstrated tuberculous lesions in three of the remaining children. In this way, from the discovery of five cases in one household, it became apparent that the entire family of each case must be studied, and this action was the first step in epidemiological control.

Skin tests followed by X-ray plates of those individuals with positive reactions failed to reveal, in the second case mentioned, any tuberculous disease or infection in the immediate family of the patient. However, two cases of the childhood type and one early adult lesion were found in the family of the sister of this patient. In each of the third and fourth cases cited and in another one subsequently observed a second member of the family was found affected. Thus, ten cases spread by family contact were demonstrated simply through cutaneous tuberculin tests, X-ray study, and observation.

Two individuals with active pulmonary tuberculosis were known at one time to be delivering milk on the village route. Substitutes were found for these workers. Also, to avoid continued dissemination in this way, it was necessary to see that all cows from which milk was supplied to the village be tested and proved free from tuberculosis. Although two of them had been tuberculosis suspects two years before, testing of all the cows giving milk distributed in the town failed to show any positive reactors. One herd was tested twice within eight months to be doubly sure. As a safeguard for the future, the council adopted a resolution requiring annual testing of all cows giving milk for human consumption within the village.

In one family a possible relationship between bovine and human tuberculosis was indicated. Two of the cases mentioned were in farm families owning dairy cattle. So it seemed advisable to have all the cows owned by every family in which one or more members had the disease tested. This was done to ascertain further any possible relationship between human and bovine tuberculosis, as well as to avoid the possibility of continued dissemination through delivery of contaminated cream to the local creamery. One infected cow was found in the herd of a family in which were two cases of the childhood and one of the adult type. These three individuals, however, were related to and had associated with one previously mentioned suffering from active disease; so it was not considered that close inter-relationship between human and bovine tuberculosis had been demonstrated.

The answer to the creamery problem was arrived at, first, through an Area Test instituted by the county commissioners of Morrison County, and, secondly, through inquiries concerning pasteurization and distribution of creamery products. In August, 1930, 35 accredited veterinarians and two state and federal veterinarians, under the supervision of the State Livestock Sanitary Board, tested all cows in the county. They obtained these results:

Total number of cattle tested	54,493
Total number of herds tested	3,453
Total number of infected herds and suspects	192
Percentage of herds infected	5.5
Total number of negative cows in infected herds	3,589
Total number of reactors	572
Total number of suspects	33
Total number of cows under feeder-quarantine	45
Percentage of infection found in the county	1.05

Retesting of suspects and cows under feeder-quarantine slightly increased the number of reactors and the percentage of infection. Seventeen cows in Morrison County and one in Todd County, adjoining, supplying cream to the local creamery were found to be infected. All these animals were disposed of, so it could be concluded that the cream supply was not infective. It still remained possible that, during the time that cream from these infected cows had been delivered to the creamery, this institution had spread the disease unwittingly, milk, cream, butter, buttermilk and cheese having been sold there. But all of these products had been pasteurized, so it was not felt that the creamery could be considered a focus of dissemination.

In another way, also, the Area Test seemed to affect the problem. It was thought that tests of all members of the families of owners of cattle found tuberculous, might disclose more cases of human tuberculosis which were possibly dependent upon the bovine type. Three of the cases already described were in the family of an owner of one tuberculous cow. Two cases were found in which the family milk supply was partially obtained from two cows which had been tuberculosis suspects two years previously. Three families with tuberculous cattle refused to be tested. The other four families owning tuberculous cattle were tested and showed two positive reactors, but X-ray examinations proved tuberculous lesions absent in these individuals. It is hoped that the families of the owners of tuberculous cattle in more distant parts of the county will be tested and examined in the near future.

One month after the cattle test was completed, the health authorities of Little Falls suggested a plan whereby all high school students in the county could have the Mantoux test applied, if their parents wished it. The Morrison County Medical Society sanctioned the plan, and Dr. E. A. Leggett of Minneapolis did the work. Though there were 948 high school students in the county, only 608 tests were applied, and a few of these subjects were grade school students. Dr. Leggett has been kind enough to permit the use here of the results of her work, which are as follows:

Total number tested	608
Total number under 10 years of age tested	29
Total number over 10 years of age tested	579
Those reacting positively to 0.1 mg. of O. T.	58
Those reacting positively to 1.0 mg. of O. T.	62
Total positive reactors under 10 years of age	0
Total positive reactors over 10 years of age	120
Highest percentage positive reactors in any group	29
Lowest percentage positive reactors in any group	5.7
Percentage of reactors in entire group	19.7

Of the 608 tests applied, 120 (19.7 per cent) showed a positive reaction. Only 118 of these suspects permitted X-ray study. Interpretation of the plates by Dr. J. A. Myers, president of the Minnesota Public Health Association, and Dr. H. A. Burns, superintendent of the State Tuberculosis Sanatorium, revealed tuberculous lesions in fifty-nine cases. Of these fifty-nine, thirty-four showed frank, unquestioned lesions, while in twenty-five the status of the lesion was somewhat doubtful. In the clinic which followed the tests and X-ray work, forty-nine cases were found with demonstrable lesions, or else were sufficiently suspicious to require further observation. Even if the latter figure is considered as the correct number of cases—and from every point of view this is the most conservative figure tenable—the work proves an incidence of tuberculosis of 8 per cent. It should be borne in mind that all of these were persons who had been believed to be well and healthy. All of them had become infected from some unknown source and each of them was or could be a potential focus of dissemination.

The work done by Dr. Leggett embraced insofar as possible only the high schools of the county. Nine of the cases found in practice had attended either the local high school or the grade school. Other cases in the series were from small surrounding villages; so, as an extension of Dr. Leggett's work, it was decided to apply the Mantoux test on as many as possible of the grade school pupils in the four neighboring communities of Swanville. After the proposed program was sanctioned by one of the state health organizations, cards were sent to the parents, requesting their permission to perform the test.

As a result, 264 Mantoux tests were applied. Of these children, thirty-nine showed positive reactions. X-ray plates were taken of the chests of twenty-eight of these reactors, and the plates were interpreted by Dr. Malcolm Hanson of the Roentgenology Department of the Lymanhurst School for Tuberculous Children. Thus, tuberculous lesions were shown in two cases, indicating an incidence of infection of 0.75 per cent of all tested, or 7.14 per cent of those reacting positively who had X-rays taken.

In addition to these tests, thirty-three von Pirquet tests were applied in routine practice. Including fifteen other cases of tuberculosis with positive von Pirquet tests, a total of forty-eight von Pirquet tests has been performed. Among these, thirty-four were positive, and seventeen of the positive subjects disclosed tuberculous lesions in the roentgenograms. These cases would naturally show a high percentage of infection, for in most instances they presented some of the cardinal symptoms of the disease.

It has been difficult to investigate the entire families of each of the students who, through the diagnostic campaigns described, were found to have tuberculous infections. Undoubtedly such a procedure would disclose more cases and would prevent further spread of the disease. This would be the last step in the study of the epidemiology of tuberculosis in Morrison County, though it is not the last work which should be done for the detection of the disease.

A summary of the work shows a total of twenty-three cases of pulmonary tuberculosis encountered in 18 months of rural practice. Seven cases were found to follow measles, and two following pertussis. Of the twenty-three cases, twelve were of the adult type, nine of the childhood type and two showed both kinds of lesions. Eleven of them were identified through adherence to a definite diagnostic schedule. Twelve were found by investigating the epidemiologic aspect of the cases found in routine practice. Eight cases were found in which the milk supply was obtained from tuberculous cattle; and two, with a milk supply from cows considered tuberculosis suspects. Twelve cases had tuberculous associates. Two hundred and sixty-four Mantoux tests were performed on grade school children, showing thirty-nine positive reactors and two cases with lesions demonstrable by X-ray. Forty-eight von Pirquet tests were performed, showing thirty-four positive reactors and seventeen cases with demonstrable lesions.

The following conclusions might be drawn:

1. As demonstrated by the facts that twenty-three cases of pulmonary tuberculosis were found in a limited rural practice within 18 months, that through the tuberculin testing of 608 high school students in one county, at least forty-nine individuals previously believed to be healthy were found to have tuberculous lesions, rural districts are promising fields for the continued fight against tuberculosis and its still excessive mortality rate.

2. If the first conclusion can be considered of any significance, every available means must be used to stimulate the interest and coöperation of rural practitioners in the fight against the disease. For the accomplishment of this objective, one of the most effective methods is the frequent repetition of a routine schedule for diagnosis available to every country practitioner and thorough enough to prove unfailingly every case of tuberculosis encountered.

The results to date of this attempt to control the disease in Morrison County could not have been obtained without the generous coöperation of Dr. Myers, Dr. Burns, Dr. Hanson and Dr. Leggett. I should like to express my appreciation to them, and to Dr. Herman Hilleboe and Dr. John Simons, for their kind assistance.

VARICOSE VEINS: SOME SPECIAL CONSIDERATIONS IN TREATMENT

Rudolph C. Logefeil, M.S., M.D.
Minneapolis

DURING the past two years, while assisting the American Medical Association Committee on Varicose Veins in conducting their clinics at the convention sessions, certain questions were repeatedly asked me by the attending physicians. In the order of their frequency, they were as follows: (1) What is the best solution to use? (2) What is the best technic? (3) How do you treat ulcers? (4) What is the best method of handling sloughs? (5) Should pregnant women be given injections? These same questions have also been most frequently encountered in conducting local clinics, especially during the past year. It is the purpose of this paper to answer these questions as accurately and completely as possible.

1. *What is the best solution to use?* This question has become more difficult to answer each year because new solutions are constantly appearing on the market which are claimed to remedy the faults of the old ones.

Bichloride of mercury, first used by Linser[1] to obliterate veins, is little used now because of its toxicity and the severe sloughing produced if some is accidentally injected outside the vein. Only one injection can be given at a visit and the small amount injected (1 c.c. of a 1 per cent solution being the maximum dose) results in only slight sclerosis, so that many injections and visits to the office are required. The same objections apply to red iodide of mercury, mercury cyanide and metaphen (the latter, however, can be safely given in doses up to 8 c.c., according to Schussler[2]).

Sodium chloride and sodium salicylate, in 20 to 40 per cent solution, were used in Europe for years, the former by Linser[3] and the latter by Sicard[4] and Forestier in Paris. Although they are still used routinely in this country in certain charity clinics, chiefly because of their low cost, most physicians have discarded them in their private practice as they produce severe pain immediately following injection, severe sloughing if injected outside a vein, and frequent "perivenitis."[5] Also, an occasional individual has an idiosyncrasy to salicylates. I use them only in "intima resistant"[6] cases and in recurrences.

Sugar solutions have been used since 1923 in the forms of glucose and invert sugar. They cause little or no pain, are non-toxic and result only in a painful, indurated area *without sloughing* if injected *outside* of a vein. Invert sugar solutions were preferred by Nobl[7] because of their decreased viscosity compared with glucose, allowing them to be easily injected in strengths of 60 and 70 per cent through a 20 gage needle.

During the past year or two, combinations of sugar solutions with sodium chloride or sodium salicylate have become very popular. The salts increase the irritant action on the intima, resulting in a firmer and higher percentage of sclerosis. The "edge" of the painful cramp is "taken off" by the addition of 1 per cent phenyl carbinol or some similar local anesthetic.

Quinine-urethane solution in 2 to 4 c.c. dosage has been advocated by Genevrier and Douthwaite[8] of England, and has been tried by many men in this country. Its chief objections are its *toxicity* frequently causing severe general reactions, *sloughing* if injected outside the vein, and its *small* maximum *dose.*

In order to determine the merits and faults of the most popular solutions, I made a careful study of their action in the same and different cases, giving at least 200 injections with each solution in some 600 different patients. The various angles studied, with the results obtained, are given in Chart 1.

Although a carefully standardized technic was used, developed after experience with more than 15,000 injections, failure to obtain a sclerosis occasionally resulted with all of the solutions. Several times with each preparation, where some solution was accidentally injected perivascularly, dilution with normal saline was omitted in order to see if a slough would appear. Unfortunately it did appear with all solutions except plain invert sugar, mercuric chloride proving the most toxic and causing a slough in two instances even after being well diluted with normal saline.

The combination of invert sugar (60 per cent) and sodium salicylate (15 per cent) seemed to be the most effective except for a rather high percentage of resulting perivenitis and a very occasional idiosyncrasy.

The combination of invert sugar and sodium chloride with some substance such as phenyl carbinol added to act as a local anesthetic and to prevent some of the usual pain, was almost as effective in producing firm sclerosis, and had a lower percentage of perivenitis.

Quinine-urethane is altogether too toxic to be used routinely. In addition to nine severe reactions and many mild ones, I had one patient who almost died after a 2 c.c. injection. Within thirty seconds after the solution entered the vein, she began to have labored respirations, cyanosis, drop in blood pressure, weak, rapid pulse, and finally delirium which was severe for six hours and did not entirely disappear for twenty-four hours. The patient had to be removed from my office to the hospital in an ambulance, where she had to remain for two days. She said she did not feel herself again for two weeks. One should always be on the lookout for these sensitive patients and never give more than 0.5 c.c. the first time and increase by only 0.5 c.c. up to 2 c.c. at a sitting.

The use of invert sugar alone seems to be limited to small veins, as failure of closure was comparatively high in the larger veins. It is an ideal solution to use here, however.

Mercuric chloride is quite toxic both systemically and locally and should be used only in patients with idiosyncrasy to salicylates and quinine-urethane, and where sugar solutions alone or in combination cause severe cramps. One must also be sure the kidneys are normal before using this mercurial.

It is difficult to select a solution that can be satisfactorily used in all cases. I have concluded from my own experience and that of some others, that the best solution to use routinely is a combination of invert sugar with sodium chloride or sodium salicylate, preferably the former. The ones I use and prefer are varichlorose and invertose compound. They can be used safely in all sizes and types of veins with a high percentage of closures if careful technic is observed. It is non-toxic, so that comparatively large amounts can be injected at one sitting (20 to 40 c.c.). If some is accidentally injected outside the vein, it

CHART 1. RESULTS OF CLINICAL EXPERIENCE WITH VARIOUS SCLEROSING SOLUTIONS

Solution	Invert Sugar† 50-70%	Invert Sugar and Sod. Sal.‡	Sodium Salicylate 20-40%	Dextrose and Sodium Chloride	Varichlorose*	Quinine-Urethane	Mercuric Chloride

†Invertose: 50-70% indicates invert sugar content by weight.
‡Invertose Cpd: Invert sugar 60% (by weight); sodium salicylate 10% (by weight).
*Varichlorose: Invert sugar 3.5 in 10 c.c.; cane sugar 2.5%; sodium chloride 1.5 in 10 c.c.; phenyl carbinol 0.86%.
The above formulæ furnished by Ulmer Laboratories, Minneapolis, Minn.

can be easily diluted five to ten times with normal saline or the patient's blood, and thus any possibility of sloughing can be prevented. In cases of diabetes, its carbohydrate value can be allowed for in the diet. If an individual is especially subject to cramps, small amounts (2 to 5 c.c.) of the solution can be used, which will usually not produce cramps or will reduce them to a minimum. Percentage of perivenitis following its use is low, and general reactions are very rare.

For the past year I have been using this combined solution routinely with great satisfaction, having now had experience in some 5,000 injections. Occasionally I find a patient who is very sensitive to cramps and does not stand pain well, and here I try plain invert sugar (50 to 70 per cent), quinine-urethane, bichloride (0.5 per cent), or small doses (2 to 3 c.c.) of 20 per cent sodium salicylate, provided the patient has no idiosyncrasy to them. It may be best to use one of the latter solutions in diabetics also. In small veins, especially the tiny, dilated varicosities of the precapillary veins, I find that plain invert sugar solution (50 per cent) works nicely. Stronger solutions such as quinine-urethane, bichloride or sodium salicylate (20 to 40 per cent) will often produce a slough even though injected intravenously in these tiny veins.

In case of recurrences, where canalization has occurred in a previously sclerosed vein, I find the wall of the vein usually thickened and the intima more resistant than before. Stronger solutions, such as sodium chloride or sodium salicylate (20 to 40 per cent), quinine-urethane or 1 per cent bichloride must and should be used in these cases. I prefer the 20 to 40 per cent sodium salicylate solution as I have found it less painful than the sodium chloride, can be given in larger amounts than quinine-urethane or bichloride, and I have obtained a sclerosis more easily with it than with any of the others. Occasionally one runs into a very stubborn case where the intima is very resistant. Here it is necessary to use very careful technic and re-

CHART 2. TYPE AND AMOUNT OF SOLUTIONS USED FOR INJECTION*

Solution	Maximal amount at one injection—c.c.	Advantages	Disadvantages	Indications for use
1. 15-50% sodium chloride	10	Nontoxic; prompt action	Marked cramping; danger of necrosis	In large, thick veins; preferable in combination with dextrose
2. 50% dextrose	20	Nontoxic; no slough; slight cramping	Not irritating enough for larger veins	For smaller, thin walled veins
3. 30% sodium chloride and 50% dextrose, equal parts	10	Nontoxic; prompt action	Marked cramping; necrosis if large amounts are injected beside the vein	Generally useful; combines the advantage and reduces the disadvantage of solutions 1 and 2
4. 50-75% invert sugar	10 or more	Nontoxic; slight cramping; no slough	Not irritating enough for larger veins	Best for smaller thin walled veins
5. 30% sodium chloride, 60% invert sugar, 1% phenyl carbinol	10-30	Nontoxic; slight cramping	Moderate cramping; necrosis if large amounts are injected outside vein	Generally useful; best solution for routine use. Combines advantages and reduces disadvantages of solutions 1 and 2
6. 20-40% sodium salicylate	5-10	Prompt action	Painful if more than 4 c.c. injected; danger of necrosis, salicylism	Generally useful with caution, best for resistant varices
7. 10% quinine with urethane	2	Prompt action; painless	Cinchonism; *anaphylactoid* reactions; danger of necrosis	Resistant varices; test for individual susceptibility
8. Sodium morrhuate	1	Nontoxic; rapid action, slight danger of slough	Marked cramping; and periphlebitis	Resistant varices; when quinine cannot be used

*After outline of A. M. A. Committee on Varicose Veins.

inject the vein every other day until sclerosis results. In one case I had to give five injections in the same vein before sclerosis was obtained.

There are some other solutions on the market which are more rarely used and not included in this study. I have listed them in Chart 2.

2. *What is the best technic?* This is a very difficult question to answer as many very good men obtain excellent results with very different technic. A physician attending the varicose vein clinic at the convention booth of the American Medical Association in Philadelphia told me that he watched five different doctors demonstrate, and all used a different technic. I told him I felt this was an advantage to him as he should be able to work out a technic for himself containing all the good points of the various demonstrations. Some men prefer to have their patients standing, others sitting, during the injection. I prefer to have my patients lying down as it makes emptying of the veins easier, and thus prevents dilution of the injecting fluid. The main thing is to get the solution in contact with the intima of the varix with the least dilution by the blood. My own technic, which I have used successfully in over 20,000 injections, is as follows: While the patient stands erect so as to distend the veins, the point of injection is selected and marked with 1 per cent mercurochrome. A rubber tourniquet is now applied well above this point. The patient then sits on a table with an adjustable leg-rest, the latter being at 45 degrees. The skin is sterilized as for any intravenous injection. A sharp sterile needle, 18 to 24 gage, according to the size of the varix, attached to a sterile glass Luer or Vim syringe filled with the solution at body temperature, is carefully inserted into the marked varix. Blood is aspirated to be sure the needle is well within the vein. The adjustable leg-rest is now raised to a horizontal position or 90 degrees. The patient carefully lies down without moving the leg. The tourniquet is now removed, relieving the distention. The assistant with index fingers now carefully "milks" the remaining blood from a section of the varix for a distance of a few centimeters above and below the needle, being careful not to disturb the latter. After assuring myself that the needle is still in the vein, I inject the solution rapidly enough to produce slight distention. I keep the index finger of my left hand over the point of the needle so I always know where it is, and can quickly feel any solution going outside the vein. The fingers of the assistant and the needle are kept in place for five minutes after the injection is completed. Upon removing the needle I apply a sterile gauze pressure pad with adhesive strips at the needle site. If the veins are large and prominent, I apply a larger non-sterile pressure pad over the section of the vein four to five inches above and below the point of injection and hold it in place with a rubber elastic bandage applied from ankle to thigh. This is kept on for two to three weeks, and removed only during the subsequent injections, which can be given bi- or tri-weekly. This allows the veins to become sclerosed in a collapsed state and produces a quicker cosmetic result. The patient is instructed to get up and go about his duties as usual in order to attain the best results.

Twenty-four to forty-eight hours after an injection one of the following results may be expected: (1) no sclerosis; (2) thickening of the vein wall without obliteration of the lumen; (3) complete sclerosis and obliteration of the vein lumen resulting in a tender fibrous cord; (4) same as (3) with perivenitis (described later). Repeated injection at the same point with stronger solutions must be made if the first two results occur.

In case of perivenitis, I suspend further injection in that leg for a few days, instructing the patient to use large, hot, wet, 25 per cent magnesium sulphate packs around that portion of the leg, as continuously as possible.

Of the various technics used, injection between the double tourniquet applied to the leg is the least desirable, to my way of thinking. Any excess of solution injected after the vein between the tourniquets is filled, is forced through the connecting into the deep veins. If large amounts are being injected by this method, there is danger of irritating the intima of the deep veins enough to cause sclerosis, especially if one should happen to be dealing with one of those cases in which the intima is hypersensitive.

In addition, I mention some general rules to follow which I have found very worth while. Large varices, especially if long, should first be injected near their lowest point and so closed from below upward. Clumps, plexuses or masses of large varices usually found over the calf of the leg are prone to develop perivenitis, so strong caustic solutions should be avoided, especially in large amounts. Sugar solutions are safest. In these plexuses an iron ring, two or three inches in diameter, may be pressed firmly around the point of puncture to keep the solution from escaping. It is hard to prophesy how a vein will sclerose, as some large veins close extensively from injections of mild solutions, while some small veins may need repeated injections of increasing concentration at the same point. It is safest to start with weak solutions.

It is safest not to give more than two injections at a sitting, that is, one in each leg. The literature shows that many of the cases of reported emboli followed where many injections were given at one sitting (Meisen[9]).

Nonsclerosis is due to poor technic, or increased resistance of the intima to the irritating effects of the sclerosing agent, an individual characteristic.

A slough may be expected in all cases where extravenous injection has occurred, except when plain sugar solutions are used. The solution in the tissues should be liberally diluted by injecting normal saline or the patient's blood, the area massaged for five or ten minutes, and a hot water bag applied for an hour or two.

The patency of the deep veins should be tested in suspicious cases by the Trendelenburg, Perthe and Pratt methods before injecting. Where the deep veins are closed, injections should never be carried out.

This form of treatment is probably inadvisable in cases of hard chronic edema or elephantiasis. These patients should be carefully studied for heart or kidney deficiency, and other vascular diseases of the extremities.

3. *How do you treat varicose ulcers?* This is certainly an appropriate and timely question, for what can be more painful and disabling than an inflamed, infected varicose ulcer? The first thing is to be sure you are dealing with a varicose ulcer, and not one due to syphilis, tuberculosis, or a mycotic infection. All varicose ulcers have varicose veins leading to them. These veins may enter from almost any side or merely run under the ulcer. They cause an abnormal circulation due to venous stasis resulting in a poorly distributed supply of oxygen to the extremity, especially the skin. Usually the reverse flow of blood in these varicosities results in an increased pressure within the veins greater than that in the arterial capillaries, as shown by Wright,[10] resulting in marked venous stagnation. This causes phlebitis, periostitis and eczema, as well as ulcers. Thrombosis, as the result of trauma or phlebitis, cuts off the circulation to an area of the skin which dies, sloughs out, and the ulcer appears. Secondary infection may now enter as an aggravating factor. It is obvious that in order to heal a varicose ulcer, *the cause*, venous stasis, must be removed. The old method was to put the patient to bed and elevate the affected limb, or remove the guilty veins by operation. This involved considerable expense, introduced an economic factor and the bed rest was not good for elderly individuals, in whom these ulcers are so common.

There are two ambulatory methods which accomplish the same result, namely, remove venous stasis. The first is injection and sclerosis of all varicose veins causing the venous stasis. If there is much inflammation, or infection about the ulcer with edema of the extremity, this cannot always be done at first. It is unwise to inject veins in an inflamed area. Where there is edema, or where the "guilty" veins lie deep under the ulcer or in the muscles, they cannot be seen and are difficult to find. Here the second method is especially applicable, namely, the use of compression to get rid of venous stasis and edema. This is accomplished by Nobl's pressure sponge,[11] or adhesive bandage. Where the ulcer is comparatively small and there is not much inflammation around it or edema of the extremity, I prefer Nobl's sponge. It consists of placing several layers of sterile gauze over the ulcer, large enough to project beyond the edge of the sponge. An ordinary good grade of rubber bath sponge is used, large enough to project an inch beyond the margin of the ulcer, and is placed on top of the gauze. The gauze can be strapped on with a couple of strips of adhesive to keep it from slipping. Any good type of elastic bandage is now applied, starting under the foot and winding upwards over the sponge, tight enough to compress the sponge to one-half of its former thickness, and then carried on up to the knee. A five yard length is usually necessary. The patient may now go on about his business. Walking on the leg thus bandaged will add a pumping effect to the existing compression effect of the sponge in ridding the underlying tissue of venous stasis. It may cause additional pain the first few hours, but as the venous congestion is diminished the pain leaves. The bandage is not removed until the patient returns in two or three days. Then the outer dressings are removed, letting the under layer of gauze next to the ulcer remain. Ten to 25 per cent silver nitrate is applied through this layer and clean gauze again added. An injection into one of the causative varicose veins can now be given before the sponge and elastic bandage are replaced. This method is repeated until all the varicose veins are injected and the ulcer healed. The sponge can then be discarded but the bandage worn for three or four more weeks. It is surprising how rapidly an ulcer will heal by this method.

When the ulcers are multiple, large and irregular, or when much edema or hard induration is present in the leg, or when associated with arteriovenous fistula, I prefer the adhesive compression bandage. It abolishes the venous stasis, diminishes the edema, reduces the size of the leg and the ulcer before any healing begins. It approximates the edges of the ulcer and presses down the margins to make it flat and relieves pain, just as the rubber sponge does. The result is that the ulcer heals rapidly beneath it. It allows the patient to be ambulatory throughout the treatment.

The technic is simple: Merely take any good grade elastic adhesive bandage and apply it from ankle to knee, overlapping one-half the width on each turn, with as much compression as the patient can comfortably stand. If there is much edema present, have the patient lie down with leg elevated until most of the edema has disappeared before applying the bandage. Reapply a new bandage every week or ten days until the ulcers are healed. Where the discharge is very profuse, I often cut a window in the bandage over the ulcer and use a rubber bath sponge as described above. This combined method has proved very helpful in certain cases. When changing the elastic bandage many varicose veins can often be seen which were hidden in edema before, and can now be injected. If irritation to the skin with eczema develops, substitute an Unna's paste cast for the adhesive bandage a few times. Wright[10] claims that by the use of the adhesive bandage alone any ulcer will heal at the rate of one square inch per week. If granulation tissue is slow in forming it can be hastened by applying constant wet dressings of thiocresol (sulphen), alternating with normal saline as described by Réimann.[12]

4. *What is the best method of handling sloughs?* Of course, being sure the point of the needle enters the vein lumen and remains within it throughout the injection will prevent sloughing. If any irritant solution is accidentally injected outside the lumen of a vein, it should be diluted at once by injecting the patient's blood or normal saline into the area in the proportion of ten parts of the diluent to one part of the irritant. Novocain (one-half per cent) can be added to the normal saline to take out its "sting" when injected. If large amounts of the irritant are injected extravenously, or if the accident occurs in areas with poor circulation, such as about the ankle or in fatty tissue, a second injection of the diluent should be made about an hour later. I usually inject one-half the amount of the diluent, massage this in for five or ten minutes, and then inject the remainder. If in doubt as to whether some of the irritant was injected extravenously, always inject the diluent. If the patient complains of burning during the injection, suspect that some of the solution is going outside the vein. If you can see or feel ballooning out of the skin with blanching about the site of the injection, you can be sure that some of the sclerosing or irritant solution has gone outside the vein. After injecting the diluent, apply a *loose* bandage over the area. Instruct the patient to apply heat here for several hours upon arriving home. Have him return in one or two days if possible. If the skin over the area of infiltration is intact and of normal color, spontaneous absorption will take place. If a hard, poorly demarcated mass is found covered with red, glossy skin which breaks on slight pressure, a slough is almost sure to develop. One can continue with the heat and apply mercury ointment, but if the mass refuses to absorb, and a necrotic area becomes clearly defined, excision should be advised. Do not wait until a gangrenous ulcer develops with the accompanying danger of secondary infection. If the excision is extended to the normal tissue, primary union usually results. Kilbourne[13] advises against early excision for fear of opening lymphatics and thus allowing spread of infection. He prefers late excision.

If the slough is small or the patient refuses excision, the gangrenous ulcer should be painted daily with a solution of gentian violet and acetone in alcohol (formula by Kilbourne[13]). I have found this reliable in preventing secondary infection. Hot, wet packs of Dakin's solution should be applied frequently each day to improve the circulation to the area and remove the necrotic material. Infra-red and ultra-violet rays aid in the same way. Sulphen solution applied as described before will hasten the formation of granulation tissue. The adhesive elastic bandage can be used in the "ulcer stage." Expect healing to be very slow with a resulting scar which is prone to contract and often become ugly.

5. *Should pregnant women be given injections?* This is a question about which very little has appeared in the literature. Most writers merely state that it is one of the contraindications to the injection treatment. This is true in Europe as well as this country. When I visited clinics abroad in 1926-27, injections were not being given to pregnant women. I understand this has been somewhat modified now. My policy up to two years ago was to use merely supportive measures, such as elastic bandages or Unna's paste casts on these patients. However, one day I had a patient referred to me by an obstetrician because of very painful varicosities about the labia majora and minora. On examination I found them to be quite large, one about the size of one's thumb. Supportive measures were of no avail here. The patient begged for relief, so I decided to inject 10 c.c. of plain 60 per cent invert sugar solution. The solution was kept in the veins for about five minutes by using pressure with an ordinary iron ring around the site of the injection. A nice non-painful sclerosis resulted. Further necessary injections were given to sclerose all the veins. The patient got complete relief from her former pain and was very grateful and happy. Since this time I have not hesitated to inject varicose veins in pregnant women, with certain restrictions, however. They are as follows: (1) Only those cases in which the varicose veins are painful or appear to be leading to the formation of an ulcer are injected. Only the painful veins are injected, as most of the apparent varicosities will disappear after the back pressure from the enlarged uterus is relieved. (2) Mild solutions, preferably invert sugar, 50 to 60 per cent, alone or in combination with sodium chloride are used. Solutions that produce severe pain or toxic solutions, especially those containing quinine, are avoided. (3) One injection is given at a sitting so the formation of a perivenitis is less likely, which, if extensive, may indirectly cause a miscarriage. No injections should be given after the seventh month of gestation. This is usually unnecessary as most painful varices appear before this time and should be injected then. Those varices that first appear after the seventh month are certainly entirely the result of mechanical pressure and will usually disappear after delivery. Supportive measures such as elastic stockings, adhesive bandages or Unna's paste casts may be used in these cases. (4) Varicose ulcers appearing during pregnancy should be treated the same as at other times. Only the veins causing or "feeding" the ulcer need be injected. Supportive measures as already described should then be used until delivery. (5) After delivery the *remaining* varicose veins can be injected. It is well to wait a month or two, or longer if they give no symptoms, before starting the injections. Contra-indications are the same as in ordinary cases, both before and after delivery.

Conclusion.—Each year new and valuable information derived from experience and scientific experimentation is appearing in the literature regarding the injection treatment of varicose veins. Five special points in treatment have been dealt with briefly, questions which seem to be uppermost in the minds of practitioners desiring to learn the treatment of varicose veins and complications.

PATHOLOGY OF PULMONARY TUBERCULOSIS

The pathology of pulmonary tuberculosis is difficult to understand because a complex terminology has been created to "pigeon-hole" certain gross appearances of the tuberculous lung. Our mental pictures of tuberculosis pathology would be clarified were we to disregard the terminology in vogue at present and in its place interpret the whole process on the basis of inflammation and repair. All stages from acute inflammation to advanced repair may be found in different portions of one tuberculous focus. Such are the conclusions of Medlar and Sasano, who studied the pathology of pulmonary tuberculosis in successive stages in animals. Extracts from the article follow.

Tuberculosis is often set aside as a disease of distinctive pathology. It is probably true that there is some chemical specificity in tuberculous infection but morphologically the lesions represent biological reactions corresponding to those of inflammation and repair observed in infectious diseases generally. Under certain conditions, for example, tubercle bacilli may incite abscess formation and under other conditions tubercle formation. Such terms as "proliferative type," "exudative type," "caseous pneumonia," "chronic fibroid phthisis," cause confusion. They do not represent "specific" lesions, but merely stages, combinations of lesions, or appearances in the course of pathological development.

The authors studied pathological changes produced in rabbits by a very virulent strain of a bovine tubercle bacillus, whose characteristics were known by previous studies. By varying the dosage of bacilli it was possible to control in a large measure the number of tuberculous lesions. As nearly as possible all other factors were controlled.

Pulmonary tuberculosis in the rabbit differs in some respects from the disease in human beings, but doubtless the fundamental pathological principles are the same in both species. Probably the chief reason for the differences observed in the rabbit and man, is that in man previous contact with tubercle bacilli has developed some resistance to the infection, whereas the experimental animals experienced their first contact with the bacilli on the day they were inoculated. Another factor is that the rabbits were given a single injection, which contained far more tubercle bacilli than any person would inhale or ingest at a single exposure to infection.

Forty rabbits were uniformly inoculated and killed at different periods. Numerous blocks of tissue were then studied microscopically.

CONCLUSIONS

1. Massive pulmonary tuberculosis in the rabbit is dependent upon the rupture of pulmonary tuberculous abscesses into the bronchial tree and inhalation of the contents of these abscesses into the previously uninvolved lung tissue. It seems plausible that this is also the method of extensive dissemination of tuberculosis within the human lung.

2. The pathology of pulmonary tuberculosis is essentially a process of inflammation and repair. Interpreted upon the basis of inflammation and repair the complex pathology becomes greatly simplified and more easily understood.

3. The complex terminology used to describe the bizarre pathology of pulmonary tuberculosis is unnecessary and confusing.

4. The term "specific" when used in connection with tuberculous lesions should be restricted to denote a biochemical, not a morphological specificity.

POSTOPERATIVE CARE OF RECTAL AND ANAL CASES

Harry F. Bayard, M.D.
Minneapolis

FROM the moment rectal or anal surgical patients are put in bed after the operative work is completed until their wounds are healed constitutes an important time, concerning which most patients have no little bit of fear. They have heard stories of severe postoperative suffering from persons who have undergone similar operations in the past; it reflects no credit upon the medical profession to have patients state that were it not for the pain they have understood such surgery entails they would have been in for treatment long before. Moreover, the frequency with which anal and rectal operative cases require subsequent reoperation may oftentimes be laid to inappropriate or neglected postoperative care.

After any anal surgery, it is well to keep hot packs to the wound as soon as the anesthesia has cleared off sufficiently to let the patient be conscious of the fact if the packs are hot enough to burn. I leave specific instructions with the nurse to apply a boric acid pack at 110° F. as soon as the anesthesia is gone and to change this pack with a fresh one hourly. It is well to keep these patients lying on their side with a pillow maintaining the hot pack in position. A change from one side to the other as the pack is changed each hour keeps their hips comfortable. The hot packs keep edema in the operative area at a minimum and tend to keep down postoperative pain by allaying spasm in the anal sphincter. Six hours of the hot pack per day is enough and this is cut down over the course of four or five days.

One of the advantages of the preoperative administration of nembutal is the long and restful sleep these patients obtain after their anesthesia has left them. Any patient experiencing any real pain is given from one sixth to one quarter grain of morphine hypodermically. Usually after the first day any pain they may have is effectively controlled by one grain of codein sulphate and ten of aspirin.

Some ten per cent of patients will have to be catheterized one or more times after such surgery. It is not advisable to allow them to go more than twelve hours without voiding although as the bladder becomes distended if an orderly or nurse will assist the patient in standing erect many catheterizations may be avoided. Patients who continue having trouble voiding are put in a hot sitz bath for twenty minutes.

At the end of forty-eight hours the patient is taken into a dressing room and under good light and ample exposure the iodoform gauze and gutta percha drain left in the anal canal at the time of the operation are gently removed. The manner in which this is done and the care exercised in loosening these dressings makes this first dressing either a nightmare or an incident. The anal canal is irrigated with some mild antiseptic such as boric acid or pure witch hazel so that the field is mechanically well flushed out. For this I use a metal tube three and one half inches long and three-eighths inch in diameter which has many small perforations throughout the distal two-thirds and has a short piece of rubber tube attached to the other end. Through this the irrigating fluid is forcibly injected. A piece of gauze is held about the anus as the fluid is injected so that any overflow may be absorbed. Mercurochrome on an applicator is gently painted over the open wound and one of the anesthetic powders supplied commercially is sprinkled about on the wound. Within a few moments the pain incidental to removing the dressing has left and the patient is comfortable again. A small piece of absorbent cotton is left tucked into the anal canal and the patient is instructed to change this with a dry piece every hour or often enough to keep the wound dry.

The first dressing having been accomplished, the worst part of the ordeal for the patient is over. He is now told he may allow his bowels to move. Usually this is all that is necessary. However, should he not have had a stool by the next day a small warm soapy enema is given. At this point in the patient's convalescence he is educated in giving himself an anal irrigation and is told to carry out this irrigation after each and every bowel movement. He is given a fountain syringe with an 18F catheter attached to the hose containing four ounces of water at 110° F. and shown how to put the catheter tip just inside the lower end of his anal canal. In this manner the water will not enter the rectum to act as an enema but will simply wash out the anal canal and provide a clean wound. These people are advised to either lie down or stand up, as sitting seems to definitely slow up the healing process.

The patient who has been on a soft diet until now is put on a full general diet and encouraged to eat. In the event that they had been troubled by constipation prior to their operation, the diet is of an anti-constipation type and dry agar may be added if the diet alone is insufficient to provide one or two formed stools each day. No effort is made to inject oil into the rectum or give mineral oil orally for the purpose of keeping the stool soft or liquid. The formed stool is the best dilator the anal canal can have and it is a mistake to sacrifice this dilating effect on the anal canal for the temporary comfort obtained by the soft stool.

Dressings subsequent to the first day are carried out much in the same manner as the first one. Other antiseptic agents such as dichloramine T solution in oil or hexamethylenamine or metaphen may be used instead of mercurochrome, depending on how much superficial infection the wound shows the first few days. The anesthetic powder may be dispensed with after the first few dressings and if the wound shows considerable secretion some dry absorbent powder as thymol iodide may be used.

Perhaps the most important thing that daily attention to the wound affords is the observation of the manner in which healing is taking place. Sulci in hemorrhoidectomy wounds must be kept open and draining externally lest they close over and an abscess form underneath; fistulectomy wounds must be kept clean and dry, but no packing left between the cut ends of the sphincters; mucous membrane must be kept from bridging across to form pockets, and granulation tissue must be kept down flat with the skin margins rather than allowed to pile up in a thick tuft. It is well to insert a finger into the anal canal frequently to make sure that the healing process is not encroaching on the caliber of the anal canal.

After healing is complete and the patient ready for discharge, advise him to keep on with the hot irrigations after bowel movement and to keep the cotton tucked in the anal canal for another three weeks. Oftentimes although the wound has healed across, a large or hard stool will rupture the thin, newly healed wound, and if anal cleanliness is not observed, infection will keep the wound open and cause all the good work up to this time to be undone.

The customary hospitalization period varies from four to seven days, at the end of which patients have been up and about long enough to feel strong again, and they have been educated in the care of their wound after they leave the hospital. An average period of three weeks has been found to be the customary time required for the simple anal wound to heal. Large fistulectomy wounds, many pilonidal cyst excisions and any complicated wound will extend the postoperative period in proportion to the size of the wound or the handicap which any complication may place upon healing.

Observation of many of these wounds has convinced me that adequate attention postoperatively makes for greater comfort and a shorter period of convalescence, as well as better end-results.

CASE REPORT

SPONTANEOUS PNEUMOTHORAX*

Arthur A. Wohlrabe, M.D., F.A.C.P.
Minneapolis

Spontaneous pneumothorax is defined as the presence of air in the pleural cavity due to internal causes and not introduced by artificial or accidental means. The term was coined in 1803, by Itard, who found this condition in necropsies of patients who had died of tuberculosis.

Laennec, the inventor of the stethoscope, first recognized penumothorax during life.

In a study of respiration in patients with pneumothorax Means and Baldwin found that one lung will do the work of two until three times the normal aeration is called for. The condition is similar to that of a diseased heart which is compensated up to a certain degree. A partial collapse may occur in both lungs at the same time but if it is complete in both death results very soon.

Etiology.—Various writers list tuberculosis as the cause of spontaneous pneumothorax in 80 to 90 per cent of cases in adults and in 40 to 50 per cent in children. It occurs more often in the male between the ages of twenty and forty. Other causes are pneumonia, gangrene, empyema, lung abscess, emphysema, hemorrhagic infarct, bronchiectasis, pertussis, diphtheria (tracheotomy), foreign body aspiration, influenzal bronchitis and unknown (idiopathic).

The idiopathic group is small. About seventy-five cases have been reported all told. Palmer and Taft reported five cases in 1930. The group includes those in which no known cause can be demonstrated. In a series of cases reported by Lemon and Barnes no known cause was found in six out of fifty cases. In this group there may be undiagnosed tuberculosis, there may have been a rupture of an emphysematous bleb, or a viscero-parietal adhesion may have torn resulting in a tear into the air cells of the lung. These cases are rarely fatal and recovery occurs in a month or six weeks. Healing should be complete within eight weeks unless complications arise. If recovery is prolonged beyond this period, the case in question should not be classed with the iodiopathic group. Two of Palmer and Taft's patients had massive intrapleural hemorrhage but recovered.

Zahn is quoted as listing the etiology of the idiopathic group as follows: (1) rupture of a vesicular bleb; (2) rupture of an interstitial emphysema bleb, the air finally reaching the pleura; (3) the direct tear of the pleura by the tug of an adhesion; and (4) senile atrophy of the pleura.

Frequently pneumothorax will occur on one side following recovery on the opposite side. Hamman has noted sixteen such instances in the literature.

Pneumothorax may be simple or complicated with exudate which may be transient or prolonged. It may be of the check valve type. When the opening closes early the air is quickly absorbed.

The actual incident in producing the tear which allows air to reach the pleural cavity may be sneezing coughing, hiccough or any sudden strain. As in the case which I am about to report there may be no definite evidence of an exciting event. It has occurred during rest or sleep.

In tuberculous cases the onset may be gradual on account of many pleural adhesions. In the absence of adhesions the onset is sudden and associated with sharp chest pains radiating to the neck or shoulder.

Diagnosis.—As a rule there is little or nothing in the history which will aid in diagnosis. Even after physical examination the exact condition will often be missed. The roentgenogram, however, is characteristic and definitely diagnostic. The type—unilateral or bilateral, partial or total, unilocular or multilocular, simple or complicated—is at once recognized. Marked depression of the diaphragm on the affected side and a displacement of the mediastinum toward the unaffected side suggests the check-valve type.

Signs and Symptoms.—Symptoms vary with the type of onset. If the onset is sudden there is pain, usually sharp and severe. It may be most marked substernally and radiate to the shoulder. Air hunger and cyanosis may be pronounced. The patient has an anxious expression and his heart is rapid. Cough may become very annoying. If the onset has been gradual the symptoms will be less marked or entirely absent. Later as the chest becomes more filled with air the patient complains of fullness and heaviness. He prefers to lie on the affected side. In a few days there may be no symptoms unless fluid accumulates.

The side involved is more prominent and the intercostal spaces are well filled out. The presence of maximum inspiratory resonance during both phases of respiration is the best physical sign. The percussion note is tympanitic. Breath sounds are distant or absent. If fluid is present there is a succussion splash and a shifting of dullness.

The right side is involved more often than the left.

Prognosis.—As a rule the prognosis in the idiopathic variety is excellent provided the storm of the sudden onset is survived and provided it is unilateral. In bilateral cases death occurs within a few hours unless one lung is only partially collapsed.

In 1902 Fussel and Reisman collected fifty-six cases from the literature. Only one of these had died. In Staloff's list of eighty-four cases of *all* varieties of pneumothorax the mortality was 57%. Recurrences either on the same or opposite sides are common.

---

*Presented before the Lymanhurst Medical Staff December 22, 1931.

Treatment.—Rest in bed is important. Strapping the affected side may give some relief.

Cough and pain should be controlled by sedatives. If fluid accumulates to any marked extent thorocentesis should be performed at intervals, a part only of the fluid being withdrawn so as not to reopen the fistula.

If the fluid becomes purulent, as is likely following pneumonia or lung abscess, free drainage should be instituted.

In the valve type of pneumothorax or if dyspnea becomes severe it may be necessary to aspirate enough air so that the lung can expand. This should be done under manometric control. Most patients adjust themselves very quickly to the new respiratory conditions and do very well under expectant treatment.

CASE REPORT

E. S., a university student, aged 26, came to my office on January 8, 1931 complaining of pain in his right chest and substernally. The pain radiated to the right scapular region and was most marked on deep breathing or on walking. There had been no weight loss, no night sweats and no hemoptysis. He tired easily and was dyspneic on exertion.

The present trouble began about December 1, 1930, with a persistent and productive cough, evidently an acute bronchitis. On December 14, 1930, he had pain in his right chest probably due to pleurisy. The sputum was examined and found negative. He continued his studies until Christmas vacation. He was apparently well at that time.

On January 1, 1931 while at home during the holidays and while resting on a couch before the noonday meal he noticed a peculiar sensation in his chest coming on after clearing his throat. The distress increased and he began to cough so persistently that he was able to finish his meal only with difficulty. He then began to notice dyspnea and palpitation. His heart rate was greatly increased. In the afternoon he walked to a physician's office and was given a sedative and digitalis. He kept quiet for a few days and returned to the University on January 6th.

Because of the persistence of his cough and substernal soreness and pain he was urged to have further studies made.

On physical examination the patient appeared somewhat undernourished. He weighed 175 pounds and measured seventy-six inches. His color was good and he appeared free from pain.

The right chest seemed more prominent than the left and was hyperresonant. There was no evidence of excursion of the right diaphragm. Breath sounds were distant or entirely absent. The heart action was normal and the rate was 80. The blood pressure was 126 systolic and 80 diastolic. Temperature was normal.

The nature of the disorder was not recognized until the patient was placed behind the fluoroscope when it became evident that he had a complete right-sided pneumothorax. A plate was made for record. There was only a very small amount of fluid in the right costophrenic angle.

Because there was a question as to when this man could return to school, Dr. Jay A. Meyers was asked to see him as consultant. The patient was advised to stay in bed and he returned to his home in another city.

On February 24th he returned to Dr. Meyers' office with a roentgenogram, taken a week earlier, which showed the lung completely expanded. There was no evidence of pulmonary infiltration or other abnormality. The tuberculin test was negative.

On March 5th, he was feeling very well except for an occasional sharp pain in his right chest. His weight was 176 pounds. On physical and fluoroscopic examinations the chest appeared normal.

On November 19th, he reported that he never felt better and had had no pain for two months or more. He had no cough. Pulse, temperature and blood pressure were normal. His weight was 176 pounds. The chest presented normal findings. On fluoroscopic examination the lung areas were clear, there was no evidence of adhesions and the diaphragm was free.

Dr. H. D. Lees of the Students Health Service examined this man on February 24, 1930. Physical and roentgen findings of the chest were normal at that time.

CONCLUSIONS

This patient should be classified in the idiopathic group because no evidence of tuberculosis was found, because his acute bronchitis of December 1, 1930, had subsided and because he made a rapid and complete recovery and has remained well to this day.

It is probable that idiopathic pneumothorax occurs more frequently than is generally supposed because it is so easily overlooked unless a roentgenologic examination is made.

PRESIDENT'S LETTER

AN essay entitled, "The Next Twenty Years," written by Hans Zinsser of Harvard University, delivered at the opening of the new Lakeside Hospital in Cleveland and published in *Science,* October 23, 1931, is of unusual interest. Zinsser pointed out that in the last twenty years the medical profession has cleaned house, as it were. Whereas in 1910 we had 166 medical schools, we now have only sixty-six, but these are turning out a vastly better quality of physician than did their predecessors. Any one who has been in contact with this stream of recent graduates can vouch for this assertion. That these young men can have attained so much knowledge and understanding of the fundamentals of medical science and at the same time so much intelligent and definite information of the new things in medicine, is a credit to their respective universities. Zinsser expects that the rapidity of growth and expansion of hospitals, laboratories, and so forth, will now be slowed down and that we must learn to take advantage of all the wonderful equipment and tools we now possess.

Nothing is so constant as change and those in authority at large institutions having to do with the affairs of medical education and research, and consequently medical service to the public, are aware of this. Economic factors, often little understood, create demands that make for changes. Our own university has taken an important step in the last year, giving evidence that our Board of Regents realizes that it is impossible for one man in the position of dean to be efficient in the purely administrative side and to carry alone also the various responsibilities that go with educational, curricular and university affairs. The creation of the office of Dean of Medical Sciences is a distinct step forward.

Dr. W. J. Mayo has advised providing shorter elective courses in the various business, academic, and scientific fields, not necessarily leading to degrees, to suit the wants and the ability of the individual. In this manner would sources of information and leadership be afforded to the public to offset the misleading teaching of demagogues.

There are many questions that puzzle the thinking man in medicine. Are there too many graduates? Is too much emphasis placed on research and investigation? Are we trying to put men through a common mould, when better study of them as material, and selection of the proper mould to suit would be wiser? The old question of full-time teaching in clinical branches no doubt will gradually be solved, but it must be solved by the medical profession in an unselfish spirit. Are the American educational foundations forcing this system on the schools?

Professor Zinsser's article is written in an interesting and philosophical strain and is well worth reading. My reason for bringing it to your attention at this time is because in such periods as these we are more likely to pay attention to affairs that affect us from without our ranks and neglect that which might be termed our internal affairs. Medicine need not fear for it is a necessary and a most valuable part of the life of our nation. Zinsser says: "The fields of our endeavor have been fertilized with a beneficence and a public confidence unheard of in the history of education." We must keep our eyes on the future, safeguard what has already been attained, steer our course straight, and remain worthy of the generous support we have had from a kindly public.

M. S. Henderson.

President,
Minnesota State Medical Association.

Vol. XV MARCH, 1932 No. 3

MANTOUX REACTIONS AND TUBERCULOSIS IMMUNITY

Science looks yearningly to the possibilities of direct immunological methods directed toward tuberculosis, such as have accomplished so much with diseases like typhoid and diphtheria. In the meantime, not a little difference of opinion appears in the theoretical attitudes of men closely applying themselves to the laboratory and clinical problems of tuberculosis. Disregarding the general immunity bestowed upon individuals by nature, resisting all inimical agents detrimental to health or inviting disease, it is worth while to bestow particular attention upon such evidence of specific immunity as is now available. We may start, therefore, with the most approved skin reaction to tuberculin—the present Mantoux test. This is probably the most efficient agent yet devised with which epidemiologists, finding reacting youngsters, are in a position to investigate their elders for open contacts (often labeled chronic cough but really benign tuberculosis).

Minnesota and the adjoining neighbor states are essentially rural. Present day skin tuberculin tests among school children, candidates for college or nursing training schools, are showing a much lower level of positives than were shown some twenty years ago, when the late Dr. Lampson made a study of a sufficient number to give his statistics widespread quotation. Those who have strongly supported the sanatorium segregation program, as well as improved general hygienic living, hope that history will ultimately connect up this lessening of childhood or early adolescent primary (Ghon) inoculations, and later bodily (allergic) response, with this effort. Theobald Smith early enunciated the idea that the bodily defense reaction in the biological sense not only defended the host but the organism as well, thus establishing a friendly alliance "for better or for worse"—at least with no desire on the part of the tubercle bacillus to immediately perish with its host, as do the rapid and fatal epidemic disorders, such as bubonic plague. In other words, this neutrality paves the way for a trench warfare in which "cavitation and cough" (consumption) provide the stage for "droplet" transmission.

At this point opinions begin basically to differ. Minnesota continues to proffer important clinical and epidemiological evidence. Geer† shows that of nurses entering a large general hospital in St. Paul only 30 per cent showed reactions to the intradermal tuberculin on entrance, but practically all are positive before completing training. Over a two-year period six nurses have developed clinical tuberculosis and only one of these showed a positive tuberculin Mantoux on entrance. This is rather striking confirmation in

---

†Geer, Everett K.: Tuberculosis among nurses, Arch. Int. Med., 49:17 (Jan.), 1932.

America on the report of Johannes Heimbeck‡ from Oslo in 1928. Somewhat alarming reports come from certain of our large eastern medical centers in terms of interns and their college and hospital residence and training. David I. Stewart of Ninette Sanatorium, Manitoba, recently writes that he considers a positive Mantoux in the adult the best specific safeguard against any fresh pickup of tuberculosis, except possible "massive infection," which, of course, every sane individual, of whatever age, would seek to avoid.

In rather direct contrast to this attitude is that of the Lymanhurst School of Minneapolis (Dr. J. E. Myers and his associate), who hold that this early Ghon regional tuberculosis response can in no way be held to be fortuitous, but that it rather prepares the stage or paves the way for a later adult response, which takes on the attitude of chronicity, dissemination, and prospect for fatality. They agree that the first contact (Ghon) need not always be mild, and admit that some constitutional dissemination with meningeal involvement can result. To those familiar with consistent autopsy revelations this cannot be denied. However, they proceed to emphasize the need of considering any and all Mantoux-positive school children, college folks, and presumably all adults, as dangerous fodder for tuberculosis, and, indeed, like gold "earmarked for export." They are, indeed, the immediate concern of zealous hygienists, if not therapeutic opportunists. It should be emphasized that this point of view is more encouraged by those whose interests are more and more epidemiological and less concerned with the aftermath of anxiety and perturbation incidental to any type of "earmarking."

Geer's statistics seem to indicate that, in contrast to the smaller private hospitals, large general hospitals pick up more concealed cases of tuberculosis, masquerading under other entrance diagnoses, from which careless spitters give not only the avenue for inoculation of previously non-reacting personnel, but also in furnishing "massive infection" to all; furthermore, that whatever relationship positive Mantoux may have to the question of constitutional immunity, those recently made positive by contact either develop a first inoculation which is not mild and self limiting, or a persistent one that induces consumption. The evidence given, however, would indicate that Geer's clinical cases were not essentially different from those accepted as the usual adult response. Pathologists are not ready to abandon the attitude of Theobald Smith, and it is difficult to convince them that viable tuberculosis germs do not abide about the original tubercles and the regional hilus caseating glands. The clinician studying children most closely is likely to attribute too much significance to the entire group on account of the relatively limited number in which he may demonstrate roentgen shadows indicative of hilus or parenchymal invasion. Reasoning from these, he would appear to be too critical of the much larger group, in which his admittedly inefficient stethoscope is little less accurate than the most definitive roentgen films. Furthermore, American clinicians up to date have given far too little consideration to Assman's epoch-making observations upon the adult exudative subclavicular extensive shadowing, beginning as dramatically as does the allergic response of the skin to urticaria or angioneurotic edema. These points have not been sufficiently considered, and we are still in the dark as to the relative proportion of these that arise from fresh external reinfection or from Herxheimer-like reactions about old childhood foci. The difficulty persists to determine the status of the individual's immunity in terms of such factors as pregnancy, intercurrent infections or biochemical disturbance. Nevertheless, the present evidence would appear to make it totally unfair to invidiously "earmark" so many young Mantoux reactors.

E. L. T.

THE ANNUAL CONGRESS ON MEDICAL EDUCATION, MEDICAL LICENSURE AND HOSPITALS

The Annual Congress on Medical Education, Medical Licensure and Hospitals, held under the auspices of the American Medical Association in Chicago on February 15 and 16, was very well attended and seemed a more interesting meeting this year than usual.

The high light of the meeting seeemd to be the discussion of the hospital situation. Dr. Ray Lyman Wilbur came out very strongly opposed to any marked extension of the federal hospital program for veterans of the World War. In fact, a great deal of the meeting seemed to center around hospitals and hospital service, and the economics of the medical profession came in for an unusual amount of discussion.

---

‡Heimbeck, Johannes: Immunity to tuberculosis, Arch. Int. Med., 41:336 (March), 1928.

In the section of Medical Education various remedies were suggested for the cost of medical care and Dr. Hugh Cabot seemed to take the center of the stage with his idea of big business in medicine. The papers quoted him liberally and his theory that corporations should deliver medical service to their employes on a large scale and for minimum cost. Dr. S. Marx White was given credit for the idea that more group practice might help the situation. Dr. Steven Rushmore, of Boston, seemed to feel that neither of these remedies would have any effect on the situation.

The topic which seemed to attract most attention, according to the attendance reported, was the care of veterans, in the Annual Conference on Hospital Service. The Chairman, Dr. Mock, opened the subject with a very illuminating discussion, asking for sincere study of the situation, taking the stand that for the veterans themselves the increased use of federal hospitals for non-service-connected disabilities would result in poor medical treatment for the veteran. Mr. Ed Hayes, member of the National Rehabilitation Committee of the American Legion, gave a very eloquent discussion of the situation, asking for the earnest coöperation of the American Medical Association in working out the best possible plan for the care of disabled veterans. Mr. Paul Fesler, President of the American Hospital Association, discussed the various conferences which have been held with the American Legion and the American Medical Association. He urged that the community hospital should be used for veterans who are now waiting for treatment because of lack of facilities of the federal hospital. He also spoke of the McClintic Bill, asking for a change in the law so that veterans might be taken care of in community hospitals by the local physicians. Dr. Elliott, of Chicago, urged greater interest in the care of cancer cases. There was considerable general discussion and the consensus of opinion seemed to be that the use of the community hospital and its development is the most important factor in the proper care of the general acute medical and surgical conditions among the veterans and that the early treatment of acute medical and surgical conditions was the greatest factor in preventing chronic disabling conditions leading to permanent hospitalization.

At the luncheon of the American Hospital Association on Tuesday plans were made for careful study of costs of the care of veterans in federal hospitals and the civilian hospitals, particularly as applied to similar groups of cases. It was expressed there by Mr. Hayes and a number of others that a good slogan next year for the American Legion and the American Hospital Association would be the standardization of the community hospitals throughout the country, looking forward to their increased use for disabled veterans at government expense. There was a general expression of opinion for continued coöperation not only nationally but in every state, looking forward to the better solution of the care for disabled veterans. It was generally agreed that the government should continue to provide facilities for the care of nervous and mental conditions, tuberculosis, and other chronic disabling conditions in veterans, but that the policy of the future should look toward the care of all medical and surgical conditions, and especially the acute medical and surgical conditions, in the local community.

C. B. Wright.

HEALTH INSURANCE

According to some recent newspaper reports there seems to be some indication that one of the recommendations of the Committee on the Cost of Medical Care of which the Secretary of the Interior, Dr. Ray Lyman Wilbur, is the chairman, will be the adoption of some form of insurance as the solution of the unequal distribution of the high cost of sickness.

Editorial advocacy of this solution to the difficulty has appeared in our columns from time to time. Health insurance is not new even in our own country. Unfortunately some insurance companies have had adverse experience in this type of insurance. The solution advocated therefore is not likely to be simple in execution.

It is perhaps not surprising that most individuals are anxious to collect from insurance policies of every kind. It is a sad commentary on the innate honesty of human nature that a large percentage of individuals are prone to exaggerate illnesses in order to collect on their insurance. Such an attitude places the certifying physician in an awkward position and too often he yields to pressure and stretches the truth as to the real disablement.

All types of insurance are abused at times by the unscrupulous. This does not seem sufficient reason for condemming health insurance as a whole. The mutual character of certain group insurance seems to exert a restraining influence on the unscrupulous which is lacking in other quarters.

Other factors will militate against the successful adoption of a general insurance program. One is the variation in the cost of medical care in various localities.

While the total cost of sickness in the country at large is not much more than it should be for value received, the indications are that the rates necessary will be more than the man with the average income is likely to want pay voluntarily. He will be inclined to take the chance that he and his family will escape serious illness. The question will then arise as to the advisability of compulsory insurance.

Ideally, health insurance should be universal. The fact remains that someone pays the cost of sickness as conditions exist at present. The cost of the care of the indigent can be found in taxes, community chests, and other forms of charity, not the smallest item being the free services rendered by the medical profession. The well-to-do, although occasionally inconvenienced by the cost of sickness, can usually take care of such emergencies. The remainder of the population, which constitutes the large majority of individuals, are the ones who require some form of insurance.

The question is sure to arise as to the advisability of the government going into the business of health insurance. Many nations have adopted some form of government insurance. Where the patient retains the right to choose his own physician seems the least objectionable form of government insurance.

The medical profession in this country is opposed to the government's providing health insurance or entering any business that can be handled by private enterprise. One has but to reflect on past experience to be convinced that governmental management is extravagant and sure to become involved in politics.

It is to be hoped that an insurance genius will bring forth some solution to the problem of furnishing health insurance to the public at large. The extensive study of the subject being completed by the Committee on the Cost of Medical Care should furnish the necessary data for this solution.

OF GENERAL INTEREST

Dr. and Mrs. Roger G. Hassett, Mankato, Minnesota, are the parents of a baby son, Roger, Jr., born January 24, 1932.

Dr. Silas Anderson has been elected new chief of staff at St. Andrew's hospital, Minneapolis. Dr. W. H. Ude was named vice chief and Dr. F. R. Gratzek secretary-treasurer.

Dr. Arthur Edward Smith, Minneapolis, has been appointed Chief Oculist for the Minneapolis, St. Paul and Sault Ste. Marie Railway, effective January 1, 1932.

Dr. Hilding Berglund has resigned as chief of the medical department at the University Medical School, effective June 30, 1933, and will spend the year beginning July 1, 1932, in absentia.

Dr. C. J. Litzenberg of Minneapolis appeared as one of twenty-four lecturers chosen from throughout the United States at the forty-eighth annual convention in Memphis, Tenn., of the Mid-south Post Graduate Medical Assembly held February 9 to 13.

Dr. E. W. F. Exley, recently associated with the Goslin Clinic, Green Bay, Wisconsin, has returned to Minneapolis, where he has opened an office at 1649 Medical Arts Building for the diagnosis and treatment of genito-urinary diseases.

Dr. J. F. McClendon, Professor of Physiological Chemistry at the University, will leave about the middle of March with his family to accept an invitation to spend a year as Visiting Professor under the Rockefeller Foundation at the Tohoku Imperial University at Sendai, Japan.

Dr. Murl J. Robertson, graduate of the University of Minnesota Medical School, 1930, who spent the past year as Interne in the Detroit Receiving Hospital, Detroit, Michigan, has purchased the practice of the late Dr. Mertens of Bayfield, Wisconsin.

Dr. Robertson is the son of Dr. J. B. Robertson of Cottonwood, Minnesota.

The University of Minnesota Medical School had as a visitor last month Dr. Ebaugh, Director of the Colorado Psychopathic Hospital, who is making a survey of all the medical schools of the country for the Mental Hygiene Board. Dr. Ebaugh is reported to have been impressed with the need for development of the work in psychiatry at the University and that a psychopathic unit is one of the great needs of the University at the present time.

The next written examination of the American Board of Obstetrics and Gynecology will be held in nineteen different cities of the United States and Canada at 2

p. m., on Saturday, March 26, 1932. The general, oral and clinical, examination will be held in New Orleans on Tuesday, May 10, 1932, immediately preceding the meeting of the American Medical Association. Reduced railroad fares will be available. For detailed information and application blanks, apply to the Secretary, Dr. Paul Titus, 1015 Highland Building, Pittsburgh, Pennsylvania.

Dr. W. I. Lillie of the Section of Ophthalmology of The Mayo Clinic is spending six weeks in Shikarpur, India, at the Seth Heranand Charitable Eye Hospital where Mr. H. T. Holland, F.R.C.S., of the Church Missionary Society Hospital, Quetta, Baluchistan, India, is holding his annual eye clinic. Large numbers of ophthalmologic operations are being performed, and Dr. Lillie, and Dr. O. B. Nugent and Dr. A. B. Cushman of Chicago, are sharing in the work. Dr. Lillie will leave Shikarpur, February 16, for Bombay. From there he will travel to Tokyo, and then across the Pacific to Vancouver. He will arrive in Rochester April 1.

Dr. Leonard G. Rowntree, Professor of Medicine, University of Minnesota, and senior consultant in medicine and director of clinical investigation of The Mayo Clinic for twelve years, has been chosen medical director of the Philadelphia Institute for Medical Research.

Dr. Rowntree will leave the Clinic in mid-summer to take up his work as director in the newly developed institute in the autumn on completion of the building in Philadelphia.

Dr. Rowntree came to Rochester in April, 1920. Previously for four years, he was director of the department of internal medicine at the University of Minnesota.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

OPERATOR OF BEYER SYSTEM CLINIC PLEADS GUILTY

State of Minnesota *vs.* Cary Beyer

On January 18, Carl Beyer, operator of the Beyer System Clinic, located in the Loeb Arcade, Minneapolis, Minnesota, entered a plea of guilty to practicing healing without a Basic Science Certificate and was sentenced by the Honorable Frank E. Reed, Judge of the District Court, to pay a fine of $200.00 or serve sixty days in the Minneapolis Workhouse. The defendant paid the fine. In imposing sentence, Judge Reed informed the defendant, in no uncertain terms, that if he were brought back before the court for a second violation of practicing healing without the proper license, he would be given the maximum penalty of one year in the workhouse with no chance to pay a fine.

For several years Beyer has been operating the Beyer System Clinic and advertising the successful treatment for diabetes, gall stones and other serious ailments, over the radio and in the Twin Cities daily newspapers. As a result of this advertising, Swen Bonderson, a farmer living near Shafer, in Chisago County, Minnesota, took his sixteen-year-old boy to the Beyer Clinic for treatment of diabetes. Bonderson paid Beyer $325.00 cash in advance, for a successful treatment for his boy. The condition of the boy did not improve and Mr. Bonderson, upon discovery of the fact that the defendant was not licensed, made a complaint to the Medical Board. Beyer was arrested on January 8, and released on $1,000.00 cash bail.

Beyer was formerly connected with the Loring Park Clinic of Minneapolis and for some time prior to 1914, he was in the patent medicine business in Winnipeg, Manitoba. He claims to be from Austria and to be a dietitian.

The conviction of Beyer marks the end of one of the most open violations of the medical laws of this state. Beyer was listed in the building directory as a doctor. The only proof discovered by the Medical Board that the defendant was a doctor, is a diploma hanging in his office indicating that Carl Beyer had received the degree of Doctor of Herbology in 1909, which diploma is absolutely worthless in this state in so far as any right of the defendant to practice healing is concerned.

Judge Reed is to be highly commended for the vigorous and emphatic manner in which sentence was imposed upon the defendant. Such a frank expression by the court as to what lies ahead of the defendant for a second violation of the medical laws of this state does a great deal more to eliminate quackery than the imposition of the sentence itself.

CHIROPRACTOR PLEADS GUILTY TO PRACTICING MEDICINE

State of Minnesota *vs.* Frederick I. Sheldon

On February 2, 1932, Frederick I. Sheldon, licensed chiropractor with offices at 800 Nicollet Avenue, Minneapolis, Minnesota, entered a plea of guilty to a charge of practicing medicine without a license, filed against him following an investigation of his activities by the State Board of Medical Examiners.

Sheldon was sentenced by the Honorable Frank E. Reed, Judge of the District Court, to a term of three months in the Minneapolis Work House. After admonishing the defendant to confine his practice to that of chiropractic and warning him that in the event of another prosecution he would be compelled to serve the three months Work House sentence, Judge Reed stayed the sentence for one year.

Complaint had been made to the Medical Board by Mr. Henry Berg, 2941 Pleasant Avenue, Minneapolis, that Mrs. Berg had been under Sheldon's care for several years and was being treated with so-called Lowenthal capsules furnished to Mrs. Berg by Sheldon. Mr. Berg claims that he was being charged $8.00 per box of 100 capsules. The prescribing or use of any such treatment by a chiropractor is a positive violation of the Medical Practice Act and resulted in the filing of a complaint against Sheldon. Mrs. Berg's ailment has been diagnosed as paralysis agitans.

A FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

Let the Doctor Decide

This is the year set for that imposing and expensive body, the Committee on the Cost of Medical Care, to write its prescriptions for the cure of medico-economic ills.

If certain recent publicity issued by Chairman Secretary of the Interior Ray Lyman Wilbur, Chairman of the Committee, may be taken as a sign, the prescription will be for a system of civilian health insurance with the government, possibly, writing the policies.

At any rate, a significant front page story appeared in February in the United States Daily, that unique publication under the management of the newspaper correspondent, David Lawrence, devoted wholly to government news, and it came direct from Secretary Wilbur's office with his official approval.

> "To relieve patients of the heavy costs of medical care in the United States," says the story, "it has been suggested that a system be worked out for the regular and orderly payments like life insurance payments, the Committee on the Costs of Medical Care announced in a statement received today from the Department of the Interior. The statement of the committee, of which Ray Lyman Wilbur is Chairman, follows:
>
> "'The costs of medical care might be modeled on a system of regular and orderly payments like life insurance in order to remove some of the difficulties attendant upon the present system of medical care and costs, it was suggested by Miss Mary Dublin in a paper just submitted to the Committee on the Cost of Medical Care.
>
> "'This important suggestion *may be of epochal significance to the health of the entire nation* (the italics are ours) was made as a result of a study of the comparative expenditures for insurance and the expenditures for medical care.
>
> "'Miss Dublin's survey is being published, the Committee points out, as one of its miscellaneous contributions and a possible help in answering the question: How may the ordinary family provide against an uncertain financial burden which may be very large in proportion to the family budget and which is likely to be uneven month by month and year by year?'"

There is more in the statement to the same general effect.

Is organized medicine ready to take a stand for or against such a proposition if it is, indeed, incorporated in the final recommendations of the Committee? Ready, that is, with figures and facts to match the glittering array that will be cited by Committee protagonists of health insurance?

Will organized medicine be ready to show by an equally exhaustive and complete study of results of national health insurance in France and Germany and England, for example, that its position on the question is founded upon equally sound and disinterested observation? The report of the Committee on the Cost of Medical Care will be a challenge to the statesmanship and stability and alertness of the medical profession. A recommendation on the part of the Committee for general health insurance will automatically create a serious problem which cannot be met by a scowling resistance on the part of the profession. If it is possible for one people to learn from the mistakes of another, then America will not fall into the error that is reducing medical practise to the football of depleted budgets, or government rules and regulations in other nations.

Health Benefits Increase Among Employees

Three hundred and fifteen commercial and industrial institutions out of a total of 602 who replied to a questionnaire sent out by the United States Public Health Service now have some form of insurance and health benefit service for their employees.

As a general conclusion of the reports of the 315, the Public Health Service cites the following paragraph:

> "As a time-tested organization attempting to meet the needs arising from certain contingencies in the life of the wage earner, the employees' sick benefit association appears to have found a place for itself in many industrial and mercantile firms. In recent years a number of them have gone beyond the original plan in an attempt to explore and develop new fields of service and usefulness to their members. One of these relatively untilled fields consists of organized effort to obtain accurate diagnosis followed by appropriate medical attention and nursing care including hospitalization if needed and to secure such in the early states of disease so that the duration of disability may be shortened as much as possible. Another important field which the more audacious organizations are beginning to till is that of disease prevention including (a) the discovery and correction of physical impairments which if neglected may cause disability and (b) health educational activity, especially in the hygiene of living."

OBITUARY

Dr. Albert E. Flagstad

1891-1932

Dr. Albert E. Flagstad was born in Minneapolis and died at the age of forty on January 26, 1932.

A graduate of the University of Minnesota Medical School, he became associated with the late Dr. Arthur Gillette and later with Dr. C. C. Chatterton and William H. von der Weyer with offices at the Moore Building, Seven Corners, St. Paul, and contributed his services to the Gillette Hospital for Crippled Children, St. Paul, until his death. His last operation, in fact, was performed at this hospital, when already ill, less than a week before his death.

Dr. Flagstad was appointed deputy coroner in Hennepin County and opened an office in Minneapolis for the practice of orthopedics two years ago, taking a suite with his brother, Dr. Carl Flagstad, dentist, at 1549 Medical Arts Building.

A member of the Hennepin County Medical Society and the Minnesota State Medical Association, Dr. Flagstad also had membership in the American College of Surgeons and the American Orthopedic Association. He was also a member of the Phi Rho Sigma medical fraternity. He is survived by his widow and daughter, and a brother, all of Minneapolis.

Dr. Flagstad was recognized for his ability in his chosen field of orthopedics, his limitless energy and his devotion to his patients.

Dr. J. A. Freeborn

1864-1932

Dr. J. A. Freeborn, prominent physician and surgeon of Fergus Falls, died at the Mayo hospital at Rochester Monday, January 25, 1932. The cause of death was cancer.

Dr. Freeborn was born in Waterloo county, Canada, in 1864, and died at the age of sixty-seven years. He was the fourth child of a large family and grew to manhood on his father's farm, attending the country school and graduating from the high school of a neighboring city in 1881. He entered a drug store at Stratford, Canada, as a clerk, and later accepted a similar position in London, Canada. In 1884, he located in Big Stone City, S. D., and opened a drug store, which he operated for two years.

He had become deeply interested in medicine and in the fall of 1886 he entered Rush Medical College in Chicago, from which he graduated in 1889. He then located at Ortonville, Minn., and practiced his chosen profession there until 1891. He then entered Bellevue Hospital and Medical College in New York City, receiving his degree from that institution a year later. He returned to Ortonville and practiced medicine there until 1896, when he came to Fergus Falls, where he had since been engaged in active practice. He was a student as well as a physician, and kept fully abreast of all the latest developments in medicine. He specialized in eye, ear, nose and throat, taking special courses in Chicago and New York and also taking X-ray work there and in Europe.

In 1891, Dr. Freeborn married Lillian Anderson, whose home was in Rochester, Minn., but who had been teaching in Ortonville. Three children were born to them: Gertrude, now Mrs. Paul Francis, of Minneapolis; Frances, now Mrs. Howard Vandersluis, of Fortress Monroe, Virginia; and Constance, now Mrs. Elmer Haugen, of Pelican Rapids.

Mrs. Freeborn died in 1915. The doctor later married Miss Agnes C. Hanson, a nurse at the Wright Hospital, Fergus Falls. During the World War, Dr. Freeborn served in the Medical Reserve corps, with the rank of captain, at Camp Custer, and his wife served as a nurse at Camp Dodge. They have one adopted son, Jack Freeborn.

Dr. Freeborn was not only an able physician, but he was highly regarded as a citizen. While quiet and unassuming, he took an active interest in public affairs, and was a member of the Rotary Club and of the executive committee of the Red Cross, and of other organizations.

Dr. John Farquahar Fulton*

1856-1932

In the passing of John F. Fulton on January 31, 1932, one of the foremost figures is lost to ophthalmology and the medical profession of the Northwest. Descending from Scotch-Irish ancestors who settled in this country about 1730, Doctor Fulton was born in York County, Pennsylvania, about fifty miles south of Philadelphia, April 20, 1856. Educated at York Collegiate Institute, he at first had leanings toward the ministry. Because of astigmatic trouble with his own eyes and consequent contact with oculists, he became interested in medicine and matriculated at the University of Pennsylvania in September, 1877. His preceptor was Dr. D. Hayes Agnew, and among the faculty during his student days were Tyson, Pepper, Horatio B. Wood, Weir Mitchell, Gross, and many other men of that day. Already possessed of a fair classical academic education, he became an excellent student of medicine and was graduated in 1880. Later Dr. Fulton was awarded the degree of Ph.D.

After an internship at the Pennsylvania Hospital and the Wills Eye and Ear Infirmary, he began practice at Altoona, Pennsylvania, then a city of 25,000, and soon established himself in general practice. Coming west to attend the A. M. A. meeting in 1882, Doctor Fulton was attracted to St. Paul and succeeded to the practice of Dr. Atwood, who was practicing ophthalmology in St. Paul and who died shortly after Doctor Fulton's arrival. He restricted his practice to ophthalmology and otolaryngology at once.

Dr. Fulton brought with him not only an excellent academic, professional, and special training but the very best traditions of medicine, and a standard of ethics toward confrères and patients which was ever a part of his naturally scrupulous and conscientious character. Thus, he soon became firmly established as the foremost ophthalmic surgeon in the Northwest during the period preceding aseptic surgery or the use of local anesthesia, and was privileged to witness the enormous evolution and development of medicine, surgical technic, and medical education during his half century of special practice. His prominence and reputation as an ophthalmologist were well deserved because of his natural aptitude, thorough medical training, outstanding personality, and conscientious devotion to his calling.

---

*Committee report read before the Ramsey County Medical Society, Feb. 29, 1932.

Very early in his career, Dr. Fulton became identified with medical organization and with teaching. He was associated with Drs. Perry H. Millard, C. A. Wheaton, C. Eugene Riggs, Albert E. Senkler, Parks Ritchie, Alexander Stone and Dr. LeGrande Denslow, in organizing the old St. Paul Medical College which later merged with the Minnesota Hospital College to become the Medical College of the University of Minnesota. He was its first professor of opthalmology and otolaryngology and was emeritus professor of ophthalmology for many years preceding his death. It is reported that largely through Dr. Fulton's personal efforts, the legislature made its first large appropriation of $100,000 in support of University medical education. When the Minnesota Academy of Medicine was organized, October 15, 1887, John Fulton became its first president. He was president of the Ramsey County Medical Society in 1893 and in 1897 was elected President of the State Society. Doctor Fulton was a member of the American Ophthalmological Society, the American Academy of Ophthalmology, and the Minnesota Academy of Ophthalmology, serving at one time as president of the latter. Also, he was a member of the Ophthalmological Society of the United Kingdom.

On April 11, 1888, Doctor Fulton was married to Edith Wheaton, a sister of Doctors Charles and Robert Wheaton, prominent surgeons of St. Paul, who, with four daughters and one son, survives him. The daughters are: Mrs. Paul Judson, Oakland, California; Mrs. Harold Booraem, of Minneapolis; Mrs. Leonard Berg and Mrs. Richard Relf, of St. Paul. Dr. John F. Fulton, Jr., is professor of physiology at Yale.

Dr. Fulton was naturally congenial and popular, ever ready to sacrifice personal interests for those of his friends, his patients or his profession. These very traits resulted in sacrifice of an enormous practice, perhaps at one time the largest personal following in Minnesota. His large practice was well deserved through his ability as a clinician, his manipulative dexterity and good judgment in ophthalmic surgery and as the result of a powerful but gracious personality. His wide range of reading in medicine and current events, combined with a remarkable memory, unfailing good humor, and a fund of anecdotes made him an interesting participant in any gathering, and a worthy companion. Even during later years, Dr. Fulton was always abreast of the times and conversant with recent medical literature, often surprising younger colleagues by his thorough knowledge of the latest contributions, not only to his

MISCELLANEOUS

THE UNIVERSITY HEALTH SERVICE

Harold S. Diehl, M.D., Director
Minneapolis

The Students' Health Service of the University of Minnesota is an organization concerning which practically every physician in Minnesota has an opinion more or less favorable or unfavorable. Few physicians, however, know intimately or accurately of the work of this department; hence this brief report of its purposes, policies and activities.

Charles Lamb was once requested by a friend to come with him so that he might introduce him to a man standing across the room. "No, thank you," replied Lamb, "I hate that man." "But," said his friend, "you should meet him. He has many admirable qualities." "That is just why I don't want to meet him," said Lamb, "because if I should know him better I might not be able to hate him any more." This is illustrative of what happens to most physicians when they become acquainted with the work of the Health Service.

The Students' Health Service was established at the University of Minnesota twelve years ago because the administrative officers and the regents of the University felt that they had a responsibility to safeguard the health of the thousands of students who come together each year upon the campus. The service first provided was only medical attention and infirmary care. Such service to students always will remain of major importance, but in recent years more and more attention has been given to the health of students who are presumably well.

STAFF

In the past ten years, the professional staff of the Health Service has increased from one physician on full time and four on part time, to ten physicians on full time and thirty physicians and twelve dentists on part time, in addition to nurses, technicians, clerks, and stenographers. All full time physicians do some teaching in addition to their Health Service duties, while the physicians on a part time basis are engaged also in private practice. This staff is able to provide general or specialized medical service which students may need.

ACTIVITIES OF THE HEALTH SERVICE

The activities of the Health Service include the control of communicable diseases; complete physical examinations and health conferences for all students who enter the University; annual health examinations for those who desre them and as a requirement for students in the colleges of medicine, nursing, dentistry and education; clinic service for medical advice or care throughout the day and emergency service at any hour of the day or night; hospital care for students in need of hospitalization; dentistry, X-rays and laboratory service.

COMMUNICABLE DISEASE CONTROL

The control of communicable diseases in the student group depends primarily upon the early diagnosis and isolation of students with communicable diseases, the supervision of contacts and suspects, and the administration of certain immunity tests and vaccines.

HEALTH EXAMINATIONS

The health examinations, both entrance and periodic, are thoroughly and carefully performed, the student spending almost an hour with the physician, in addition to the time required for filling out the history blank, performing vision and hearing tests, taking weights and measurements, and doing laboratory work. Upon the completion of the physical examination, the physician discusses with the student his health and habits of living, and gives such advice and counsel as seems indicated, a summary of which is given to the student in the form of a health prescription. Follow-up studies to determine the significance of findings noted during these examinations are made by the Health Service in case students do not follow the suggestion that they go to their private physicians for such service.

Each year these examinations lead to the discovery of a few serious diseases and many minor defects. In the group of students who entered the University during the present school year, routine X-ray plates of the chest were taken on all students who showed positive reactions to tuberculin. These led to the diagnosis of one case of far advanced, five of moderately advanced, and nine of incipient tuberculosis. In another group of five thousand students who received periodic examinations during the past two years, ten cases of syphilis were discovered as a result of routine Wassermann tests. Each year, certain students are found to have diabetes, nephritis, or heart disease, while others who thought that they had such diseases have been assured that the diseases do not exist. Minor defects such as malnutrition, dental caries, abscessed teeth, impairments of hearing, defective vision, hernias, etc., are found in a large percentage of the students examined. As a result of these examinations, students with major illnesses are placed under treatment, and many of the minor defects are corrected. In addition, the Health conferences between physicians and students are probably the most effective means of health instruction in the University.

OUT-PATIENT SERVICE

The out-patient dispensary or clinic of the Students' Health Service makes medical service easily available at any time. In this department, students may consult physicians either in general medicine or in the various specialties. An average of about two hundred and fifty calls per day are made voluntarily by students to this department. Most of these calls are for very minor illnesses, in fact, probably not ten per cent of these students would ever reach physicians if the Health Service did not exist. The other ninety per cent would receive their medical advice from friends, landladies, or the corner drug store. Yet, it is only by encouraging students to report with illnesses which they may consider minor, that it is possible to make early diagnoses of serious illnesses or contagious diseases.

HOSPITAL CARE

To the Health Service hospital, any University student may be admitted, but the policy is to advise students who have family physicians to go home and place themselves under their care. Students living in dormitories or rooming houses are usually admitted directly to the Health Service hospital, but if the illness seems serious or if an operation becomes necessary, the student is urged to get in communication with his family or family physician and find out whether they can arrange to have this specialized service provided in one of the private hospitals of the city. Since the University makes no distinctions between students on a financial basis, it has never seemed desirable to attempt to set up economic standards for the admission of students to the Health Service hospital. On the other hand, if it is consistent with their welfare, the Health Service always urges those students who can afford to do so to secure medical service from their private physicians.

This hospital service for students, or it might better be called infirmary service, because, under ordinary conditions, very few of these students would be sent to a hospital, is of the greatest importance to students who are sick away from home. The expressions of appreciation from parents, physicians, as well as others, leaves no doubt in regard to the feelings of relief and security which parents have because of the facilities which the Health Service makes available to their sons and daughters. As I am writing this paper, forty-five students are patients in our Students' Hospital. Most of these have respiratory infections; several have had injuries; two probably have pulmonary tuberculosis; one has scarlet fever; two, broncho-pneumonia; three, gastro-enteritis; three have had operations, etc. I wonder, as I look over the list, where these students would be and what sort of care they would be receiving, if the University had not provided a Health Service to care for them. A few probably would be in hospitals; the boy with the scarlet fever, who lived in a dormitory but was isolated with a sore throat three days before the rash appeared, doubtless would be in the contagious section of the Minneapolis General Hospital, but until the rash appeared he certainly would have remained in his dormitory, exposing many other students; most of the others probably would be in bed in dormitories or in fraternity or rooming houses. What an undesirable situation that would be and how our University tolerated it as long as it did is difficult to understand. The character of the professional service and hospital care which the Health Service provides for students is such as we would wish for our own sons and daughters attending college away from home.

SPECIAL DEPARTMENTS

The pharmacy, X-ray and dental departments of the Health Service are operated on a self-supporting basis, fees being charged for the services rendered. The purpose of these departments is to provide such diagnostic, corrective and therapeutic services as are necessary to safeguard or improve the health of students.

SOURCES OF REVENUE

The entire operating budget of the Health Service comes from the students. Approximately two-thirds of the total budget is allocated to the Health Service from the incidental fees which students pay, there being no special health fee; the remainder accrues from certain fees which are collected for individual services such as X-ray, dentistry, drugs, glasses, use of the operating room, board and laundry in the hospital after two days, etc. No charges are made for professional services rendered by members of the staff.

RELATION OF HEALTH SERVICE TO PRACTICING PHYSICIANS

The Health Service desires to coöperate in every way possible with physicians engaged in the private practice of medicine. Any information which we have about the health of students, we are glad to make available to the private physicians of these students and we welcome information from physicians about students who have been under their care. Certain procedures, such as certification for athletics, military drill, physical education, teachers' certificates, etc., are responsibilities which this department must assume, but in certain cases the family physicians must have information which would be distinctly helpful in passing upon these cases. Occasionally students come to us who are under the care of private physicians. In such situations, we always desire to coöperate with the student's physician if we learn of his interest in the case.

Some physicians seem to think that the activities of the Health Service detract materially from the income of physicians in this community. Actually, however, I firmly believe that the balance is on the other side. True enough, a few physicians would receive fees from students for medical services which are now rendered by the Health Service, but the total of this amount probably would be but a small fraction of the $62,000 which the Health Service is paying this year to physicians of Minneapolis and St. Paul for service to students.

Another report occasionally heard by physicians is that the Health Service frequently operates upon students who can well afford to pay the fees of private surgeons. The facts are that, although practically all of the students who are operated upon at the Health Service are self-supporting, an occasional student who might be able to pay probably does receive a major operation here without charge. The welfare of the student, of course, must be the first responsibility of the department. On the other hand, since no fees are charged, the Health Service has nothing to gain by the performance of operations and no member of the staff wishes to assume responsibility which he can properly pass on to someone else; furthermore, it is our desire to coöperate and not compete with physicians and surgeons in practice. These are the reasons for our policy of referring students with major illnesses to private physicians whenever possible.

Important as such immediate relationships of this service seem to be to the practice of medicine, the remote results of this work, we believe, contain infinitely greater possibilities, and all of these tend as the of benefit to the medical profession as well as the public. The medical experience and health education which some six thousand students are unconsciously receiving each year from thorough physical examinations and health conferences, the custom of an annual physical examination which hundreds of students practice and the habit of seeking medical service promptly when ill, which most of the twelve thousand students learn while here, cannot fail to exert a very real and favorable influence upon the subsequent health and medical practices of these young men and women. Certainly most of these students leave the University with a better understanding of modern medicine than they ever had before and they no longer will be satisfied with slipshod medical practice or superficial physical examinations. Charlatans and quacks will have but little chance of ever selling their particular brand of therapeutics to these students.

In conclusion, I should like to state that I believe that every activity of the Health Service is fully justified, that physicians of this community receive more income through the Health Service than they would from the student body if the Health Service did not exist, that the end-results of this work will react greatly to the advantage of both the public and the medical profession; and finally, that the Health Service always considers it a privilege to hear from and coöperate with family or private physicians in the proper care of students attending the University.

MOST GOVERNMENTS ARE INEFFICIENT OR CORRUPT—SOME ARE BOTH*

EDWARD H. OCHSNER, M.D.
Chicago, Illinois

One of the very first questions that naturally arises is: Have any of our governmental agencies so conducted themselves in the past as to make it reasonably safe for us to entrust so stupendous a function as universal social insurance to any branch or department? I maintain that most of our local as well as state governments are inefficient or corrupt, and some are both.

Let any one who doubts the correctness of this statement spend a little time to look around with a critical eye and observe how most local governments, the various departments of the state in which he lives, and the departments of the federal government are conducted, and I am convinced that he will find more inefficiency than he has ever dreamed could exist. If he does not personally know of corruption and inefficiency in government, let him but scan one single daily newspaper regularly for a month in order to be convinced. And what else can one expect who is at all familiar with politics as it has been played and managed in these United States in the year 1931—the manner in which most men secure their nominations and later their elections, and to whom they are beholden when they take office?

We have all seen the statement repeatedly in the public press, but have never seen it successfully refuted, that in many of the political subdivisions of our country only sixty per cent of the taxes collected are effectively spent, the remainder being frittered away, wasted or stolen. This inefficiency and corruption is due to many causes, of which some of the more important are:

---

*One of a series of articles appearing in state medical journals on various phases of socialized medicine.

The fact that so far no formula has been discovered according to which the most efficient, honest, industrious and worthy members of the community can be secured for public office. Nor has there been any method devised whereby spoils, politics, favoritism, pull, nepotism, waste and graft can be eliminated with even a reasonable degree of certainty. The individual who could solve these two problems would not only be the greatest benefactor of the human race but the wisest man the world has so far produced. Plato tried to solve this problem twenty-three centuries ago when he wrote his Republic. For a time he actually thought he had found a solution. He prevailed upon the King of Syracuse to adopt his plan and put it into operation. The King tried it for a while, tired of it and sold Plato into slavery. Some good friends ransomed him. After that he was not so sure that his scheme would work in practice. Things are not much different today than they were in the time of Plato—only worse. Worse because of the increase in population, resulting in larger governmental units, the enormous increase in the number of those exercising the franchise, the increase in the percentage number of ignorant voters and the ever increasing astuteness and finesse of our practical politicians.

Inefficiency and corruption is so common that we have become callous to it. We are annoyed by it, we grumble and complain mildly about it, we pay our ever mounting taxes if we have anything with which to pay and "let it go at that." It almost seems as though we humans had adopted David Harum's dog philosophy and were applying it to ourselves. He said:

"A certain amount of fleas is good for a dog, it keeps him from brooding on being a dog."

The best illustration of governmental muddling in general is to be found in the mess most governments of the world have made of themselves during the past twenty years. As examples, we need but call attention to the virtual bankruptcy of Germany and of Austria, the maladministration in Russia, the revolutions in Spain, China, Central and South America, the dictatorships in Poland and Italy, and, when we come nearer home, the general lawlessness in the United States with its murders and kidnapping for ransom; conditions in the city of New York as diclosed by the Seabury Investigation; the virtual bankruptcy of Chicago and Philadelphia, and the near bankruptcy of many other governmental units.

Let us study conditions in our own country a little more in detail in order to determine whether it would be wise or even safe to entrust the federal, state and local government, or any one of them, with supervision over the private lives of its citizens. (This phase of the problem will be taken up more in detail in the future installments.)

NOTE ON MIGRAINE

E. C. Hartley, M.D.
Saint Paul

Clendening* refers to a number of writers who comment upon duodenal and upper intestinal tract stasis during attacks of migraine. He himself says: "This condition of stasis, however, has long been known and the feeling is peculiar to all sufferers of the disease. A fair proportion of them know that if they get a cathartic, or some analgesic drug such as aspirin, in the stomach during the prodromal stage they may abort an attack, but if they wait until this attack is in full swing, any medicine which is swallowed will stay in the stomach and later be vomited. Translating these clinical facts into physiologic language, it means that if the drug is taken before the gastrointestinal stasis occurs, then it will be moved into the intestines and absorbed and thus have some action, but if taken later when the gastric and intestinal musculature is paralyzed, no absorption occurs."

Obviously, any symptom which appears early enough to mark the point at which medication could be taken early enough to insure its absorption will be of primary value in effective treatment. The writer (whose chief interest in migraine is the fact that he has felt its cyclic visits with considerable gloom) has identified one symptom which satisfactorily marks this point in himself; upon inquiry among friends similarly afflicted, the same symptom was recognized.

This symptom, marking the point at which oral medication may be taken with a reasonable hope of relief, is a sensation of gagging; the patient makes efforts to clear his throat, not violently or excessively, but still definitely enough so that he will recall the sensation if asked about it, but, as a rule, not otherwise. Once recognized the patient must not delay taking his medicine, for gastric inertia invariably sets in within a short time and the attack will run its customary course.

Calcium in various forms has been used for some time in the treatment of migraine. The writer has found that calcium gluconate, one or two heaping teaspoonfuls in water, will uniformly abort an attack. All that is felt is a sensation of tiredness, not unpleasant; there is no nausea, vomiting, depression or headache.

---

*Clendening: Modern Methods of Treatment. 4th Edition. C. V. Mosby Co.

THE BACTERIOLOGY OF LISTERINE OR WAS THE LANCET REPORT RELIABLE?

According to the Lancet (London) report: "The actual number of micro-organisms killed in 15 seconds by undiluted antiseptic exceeds that claimed by manufacturer," that is, 200,000,000 in 15 seconds. Such a statement means little. The Lancet report *does not* bring out what the A. M. A. report does: diluted Listerine is no more bactericidal than water. Even full-strength Listerine is an exceedingly weak germicide. (Jour. A. M. A., November 14, 1931, p. 1467.)

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service.

The Minnesota State Medical Association broadcasts weekly at 11:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of March will be as follows:

March 2—Personal Hygiene—Fresh Air and Sunshine.

March 9 —Cleft Lip and Palate.

March 16—Prevention of Bronchiectasis.

March 23—Fracture of the Spine.

March 30—How Does Cancer Begin?

AMERICAN COLLEGE OF PHYSICIANS

The sixteenth annual Clinical Session of the American College of Physicians will be held in San Francisco the week of April 4, 1932.

The program will include some sixty addresses covering the more recent advances in the field of internal medicine. Among other medical subjects which will be discussed will be the following: hypertension, pulmonary arteriosclerosis, edema, leukopenia, arthritis, and diseases peculiar to the West Coast. The recent outstanding progress in our knowledge of the involuntary nervous system will be presented.

Clinics in the various local institutions will occupy the morning hours. History of medicine which has received growing interest of late will occupy one of the morning sessions.

While the session is intended for Fellows and Associates of the College, an invitation is extended to all physicians to attend. The guest fee of $15.00 includes a year's subscription to the Annals of Internal Medicine in which the papers will be published. General practitioners as well as internists will find the meeting profitable.

Dr. S. Marx White, Minneapolis, is the incumbent president and Dr. George Morris Piersol, Philadelphia, the general secretary.

MINNESOTA STATE MEETING

Technical exhibits will be the center of interest during a large share of program time at the 1932 meeting of the Minnesota State Medical Association and the Minnesota State Hospital Association scheduled for May 23, 24 and 25 at the new St. Paul Auditorium.

This will be the largest joint meeting of medical and hospital personnel ever gathered in the Northwest. Representatives of eight states, including Montana North and South Dakota, Nebraska, Wisconsin, Iowa, Wyoming and the Winnipeg Medical Society of Manitoba, Canada, have already indicated an intention to attend.

The enlarged scope of this meeting which, in its scientific and technical exhibits and its demonstrations as well as in one large joint evening meeting takes in both great associations, has occasioned a number of program departures.

One special feature of the 1932 arrangement calls for two one hour sessions each day and an open Monday evening session in the technical exhibit hall. This is for the especial purpose of giving every visitor a chance to examine all exhibits. The most interesting program novelty will undoubtedly be the forty table demonstrations to be held during the two one hour exhibit hall sessions. These demonstrations are to be sufficiently varied in subject to interest everybody, and those who are not attending the demonstrations may take advantage of the time to study the scientific and technical exhibits. These last are to be especially emphasized at this meeting.

Twice daily the demonstrations will be conducted from 10:00 to 11:00 A.M., and from 2:00 to 3:00 P.M., by twenty of the best qualified men in the state. The Committee on Clinical Demonstrations and Exhibits announces that it is taking every care to guard against any repetitions or overlapping in subjects. Among those selected to date are: Fungi; the Ascheim-Zondek Test; the Electrocardiograph; Undulant Fever; the Allergic Skin Test; Urine Typing of Pneumonia; X-ray of Juvenile Tuberculosis; Gallbladder Technic; the Tuberculin Skin Test; Cauterizing the Cervix; Brain Model; Localization; Ulcer X-ray; Eyegrounds; Fracture Demonstration. Final choice of those who are to give the demonstrations will be made at the February meeting of the Committee on Scientific Assembly.

Both scientific and technical exhibits will have the benefit of the unusual space and presentation facilities of the new Auditorium. The committee in charge already reports an unusual number of entries. The gold medal for the best scientific exhibit will be offered again for the third consecutive year by the Southern Minnesota Medical Association. This medal was won in 1930 by Dr. Leo Rigler, University of Minnesota, and in 1931 by Dr. William P. Herbst of Minneapolis and Dr. R. K. Ghormley of Rochester. Competition is expected to be keen in 1932 for this medal.

A series of six clinical pathological and clinical radiological conferences has been arranged as another 1932 novelty for the Monday afternoon program. Drs. E. L. Tuohy of Duluth, Harold Robertson of Rochester, John Noble of St. Paul, B. R. Kirklin of Rochester, and Leo Rigler have already been assigned to conduct the conferences, each of which will occupy forty minutes of program time.

Hospitalization and Medical Care of Veterans will be discussed before a large joint meeting of the hospital and medical associations Monday night in the theater of the Auditorium. Speakers for this meeting which is to represent hospital men, the medical profession and lay trustees of hospital boards include the Reverend Father Alphonse Schwitilla, president of the Catholic Hospital Association; Mr. F. R. Bigelow, president of the St. Paul Fire and Marine Insurance Company; Mr. E. V. Cliff, Ortonville, National Executive Committee member of the American Legion; and, if his engagements permit, Dr. Olin West, secretary of the American Medical Association, Chicago.

IOWA STATE MEDICAL MEETING

The members of the Minnesota State Medical Association are cordially invited to attend the annual session of the Iowa State Medical Society, to be held in Sioux City, Iowa, May 4, 5 and 6. The program, which is an especially strong and interesting one, begins at 8:00 a. m. on Wednesday, May 4, and concludes at noon on Friday, May 6. There will be an hour and a half of medical and surgical clinics, and symposia upon the following subjects are included in the program: kidney, blood diseases, neurological conditions, cancer, and pediatrics.

Presentation of a membership card in the Minnesota State Medical Association will admit any physician from this state to full privileges in all scientific sessions.

MINNESOTA RADIOLOGICAL SOCIETY

At the winter meeting of the Minnesota Radiological Society, held at the University Hospital in Minneapolis on Saturday, February 13, 1932, the following program was presented:

CLINICAL-PATHOLOGICAL-RADIOLOGICAL CONFERENCE

Conducted by Dr. W. A. O'Brien

Assisted by Drs. B. Pearson, O. Randall, R. Koucky

1. Ewing's Sarcoma of Bones
   Discussion by Drs. W. Cole, C. Hansen
2. Multiple Myeloma with Intestinal Obstruction
   Discussion by Dr. O. H. Wangensteen
3. Carcinoma of Breast with Multiple Metastases
   Discussion by Drs. K. Stenstrom, O. Campbell, L. Rigler
4. Carcinoma of Antrum with Peripheral Metastases
   Discussion by Drs. W. Peyton, K. Stenstrom

Relative Value of Stereoscopic and Single Films in the Routine Examination of the Chest—Dr. Frederick B. Exner

Studies on the Routine Examination of the Chest in Students—Dr. Harold Diehl

Anomalous Lobes of the Lungs—Dr. L. G. Erickson

Observations on Intra-pleural Pressure in Massive Pulmonary Atelectasis—Dr. Rudolph Kocky

Radiation Therapy of Neuritis—Dr. John J. Eneboe

Fractures of the Sesamoids—Dr. Jacob Sagel

Methods of Radiation Therapy of Carcinoma of the Esophagus—Dr. C. O. Hansen

Intraperitoneal Herniæ, Preliminary Report—Dr. Frederick Exner

The Use of Thorotrast in Roentgen Diagnosis, Preliminary Report—Dr. L. G. Ericksen

ADDRESSES

The Recent Literature on the Classification and Treatment of Bone Tumors—Dr. W. A. O'Brien, Professor of Pathology, University of Minnesota

Cholecystographic Studies on the Emptying of the Human Gall Bladder—Dr. E. S. Boyden, Professor of Anatomy, University of Minnesota

The next meeting of the Society will be held in Saint Paul, May 23, 1932.

RICE COUNTY SOCIETY

The Rice County Medical Society met February 12, at the Blue Bird Inn at Faribault as guests of Dr. and Mrs. D. W. Francis. The affair was given in honor of Captain O. T. Francis, U. S. M. C., brother of Dr. Francis, who has been in command of the government radio station in Shanghai for the past two years.

Mr. Lester Swanberg reviewed recent news from the Far East, and Captain Francis talked about China.

Dr. C. W. Plonske, secretary-treasurer, presented his annual report showing 100 per cent membership in the society and a balance of $115.29 in the society treasury.

WOMEN'S AUXILIARY
Minnesota State Medical Association

President—Mrs. James Blake, Hopkins
Chairman Press and Publicity—Mrs. Glen R. Matchan, Minneapolis
Editor—Mrs. Horatio B. Sweetser, Jr., Minneapolis

WEST CENTRAL MEDICAL AUXILIARY

The mid-winter meeting of the West Central Medical Auxiliary was held at the Merchants' Hotel at Morris, January 13. The program included an explanation of the Shoulders Bill, given by Mrs. Herman Linde of Cyrus. Two new members, brides of this fall, joined the Auxiliary.

HENNEPIN COUNTY MEDICAL AUXILIARY

At the January meeting the Woman's Auxiliary of the Hennepin County Medical Society voted a three hundred dollar student loan fund for medical students at the University of Minnesota, this fund to be administered by the Dean of the University. Dean E. E. Nicholson of the University came to the meeting and explained the method of handling such funds. At this meeting Mrs. Walter Marcley gave a very interesting talk on international relations, with some discussion of the disarmament conference.

RAMSEY COUNTY MEDICAL AUXILIARY

To raise money for their Student Loan Fund, the Ramsey County Medical Auxiliary held a card party, Friday, February 5, in the County Society rooms.

The members are busy making arrangements for the coming State meeting to be held in Saint Paul in May.

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of Dec. 9, 1931

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, December 9, 1931. Dinner was served at 7 o'clock, and the meeting was called to order at 8 o'clock by the President, Dr. J. S. Gilfillan.

There were 47 members and 1 guest present.

Minutes of the November meeting were read by the Secretary and approved as read.

The annual election of officers was held, resulting as follows:

President, Dr. J. C. Litzenberg, Minneapolis.
Vice President, Dr. C. D. Freeman, St. Paul.
Secretary-Treasurer, Dr. R. T. LaVake (re-elected).

The scientific program of the evening was as follows:

Dr. A. E. Wilcox (Minneapolis) reported a case of "Traumatic Subcapsular Hemorrhagic Cyst of the Spleen" as follows:

The patient, H. H., age 26, reported July 31, 1931, complaining of pain in the upper left quadrant along the costal margin.

His immediate history was that in the morning of the above date he was carrying a crate of machinery and struck his left side against the edge of a table. His symptoms did not seem to be severe; in fact, he came for observation at the insistence of his employer and not on account of the severity of his symptoms. Physical and X-ray examinations were negative and the condition was considered of a trivial nature and diagnosed as a contusion of this area. He continued to work, but reported at the office five times the following month, during which time he was still at work, but complained periodically of some pain in his side.

On September 14, 1931, in the evening, he noticed for the first time a swelling below the left costal margin and the pain increased. The following day he reported at the office, at which time a palpable swelling was noted occupying a position below the left costal region. The swelling appeared to be four or five inches in diameter and the mass was tender and marked friction rub was noted on deep breathing and definite dullness on percussion. The mass was smooth and round, but gave to the palpating hand the sense of fluctuation. The clinical impression was enlarged spleen.

X-ray studies were made and the report was as follows: "Fluoroscopic examination was made of the stomach and duodenum following the ingestion of a barium meal. The stomach is displaced markedly towards the right so that it lies almost in the midline with also marked displacement anteriorly by a mass which bulges in the left upper quadrant and which apparently also causes a splinting and elevation of the left diaphragm. The stomach and duodenum otherwise are normal. Films were made of the abdomen with the barium-filled stomach. The marked displacement of the stomach is again demonstrated. The mass occupies the entire left half of the abdomen with the stomach displaced well beyond the midline. The kidney shadow can be fairly well made out although it does appear to be somewhat enlarged. The shadow of the psoas muscle can also be differentiated, but is somewhat overshadowed by the abdominal mass. The nature of the mass can not be further determined. Its location and possible association with trauma would indicate that it represents a retroperitoneal hemorrhagic cyst. This type of appearance is occasionally associated with a large hydronephrosis so that the process may be in the perirenal region. I do not think it arises in the spleen. At 24 hours the transverse colon shows marked downward displacement including the splenic flexure. The entire study most strongly suggests a retroperitoneal mass.

"Conclusions:

1. Large left abdominal mass.
    a. Possible retroperitoneal hemorrhagic cyst with or without involvement of the kidney capsule.
    b. Possible large hydronephrosis.

"Films were made of the region of the kidneys. The right kidney is entirely within normal limits. The left kidney appears to be definitely enlarged and its outline fuses with the large mass palpable in this region from which its contours can not be separated. These films show some obliteration of the psoas shadow, but there is no evidence of spasm of the psoas muscle. This study suggests the same conclusions as on the previous examination and most strongly indicates a kidney mass."

On September 17, 1931, the patient was admitted to the hospital. Temperature was normal, pulse 85, respiration 18. Urine was negative. Hemoglobin 70 per cent. Erythrocytes 4,156,000, leukocytes 10,800, P. M. N's 70 per cent, large lymphocytes 18 per cent, small lymphocytes 12 per cent. Other general physical examination appeared to be negative and unimportant.

Revised pre-operative diagnoses were:

1. Hemorrhagic cyst of spleen, traumatic.
2. Retroperitoneal hemorrhage.
3. Hydronephrosis.

An exploration was advised. Under spinal anesthesia, 200 mg. novocaine, supplemented with nitrous oxide, a left rectus incision was made. When the peritoneum was opened a large, smooth, cystic tumor which proved to be the spleen was found. The spleen grossly appeared about the size of an adult's head. There were marked adhesions to the anterior peritoneal wall, diaphragm, omentum, and stomach. These adhesions were carefully separated and with considerable difficulty, and this only after rupturing of the capsule and allowing some of the encysted fluid to escape. The pedicle of the spleen was gradually isolated and ligated in sections with chromic catgut, being careful to avoid important surrounding structures, mainly the tail of the pancreas and stomach. Some of the adhesions bled sufficiently to warrant ligation of the stumps, but in general the field was fairly dry when enucleation was completed. The abdominal wound was closed in tier sutures without drainage, no other pathology having been encountered.

The post-operative period was uneventful and, with the exception of hypodermoclysis and sedative for pain, no difficulties were encountered. Wound healed by first intention. Patient left the hospital, October 1, 1931, and returned to work November 9, apparently free from symptoms.

The specimen presented shows a spleen weighing 360 grams, after the fluid was removed. Before the capsule was ruptured, as stated above, the appearance was about the size of an adult's head and undoubtedly contained approximately two quarts of fluid. The capsule is markedly thickened and shows evidence of marked adhesions.

Final impressions were that there had been a contusion of the spleen followed by slow, progressive hemorrhage or that there had been a secondary hemorrhage which accentuated his symptoms at this late date. However, the thickened capsule would suggest that the affair had been slowly progressive from the start.

The patient was of the tall and markedly asthenic type, in which the spleen may occupy a position below the costal margin, making exposure and susceptibilty to trauma more marked.

DISCUSSION

Dr. F. E. B. Foley (St. Paul): In the first place I would like to congratulate Dr. Wilcox on two points: first, on the presentation of such an unusual case, and second, on having put the spleen first in the order of possible diagnoses.

I am interested particularly from the standpoint of the differential diagnosis between the condition found by Dr. Wilcox and a process in or about the kidney.

His remarks concerning the roentgenologic examination of the kidney are worthy of some comment. It is said that accumulations around the kidney obliterate the psoas shadow. In twenty-five or thirty cases of perinephric abscess which I have observed, the psoas shadow was obliterated almost regularly. On the other hand the psoas shadow may be obliterated in the absence of perinephric abscess, inflammation or hemorrhage. Any process that gives an increased density over the psoas border, such as hydronephrosis, renal tumor or solitary cyst, may obliterate the psoas shadow. Finally the psoas outline may fail to show even in good films in the absence of any pathologic process whatever. For these many reasons the sign is of dubious value and not to be relied upon.

The really valuable criterion in differential diagnosis would be a pyelogram. I did not understand that a pyelogram had been made in this case and without one I rather marvel at Dr. Wilcox's diagnostic acumen in having recognized this as a tumor of the spleen.

Dr. Irvine McQuarrie (Minneapolis) read his Inaugural Thesis entitled, "Some Recent Observations Regarding the Nature and Treatment of Epilepsy in Children."

I wish to thank the Academy for the honor of my election to membership. It is a pleasure for one to belong to a group such as this, which is composed of men representing all branches of medicine and surgery.

ABSTRACT

The results of some recent studies on the blood lipids and on the mineral and water exchanges in epileptic children were presented. It was shown that under certain conditions cessation of grand mal seizures in severely epileptic children follows the establishment of a deficit in the body water, whereas rehydration rather promptly leads to their recurrence. Data were presented to show that typical seizures can be induced at will in a high percentage of mildly epileptic patients during their usual intervals of freedom from attacks and while they are on relatively high water and low mineral intake by sustained pituitary antidiuresis. Convulsions usually occur under these conditions only after the amount of water retained is equal to from two to five per cent of the body weight. That dilution of the extracellular body fluids under these conditions is an important factor in the induction of seizures is indicated by the fact that a low mineral intake favors their occurrence, whereas ingestion of just sufficient NaCl to prevent dilution tends to interfere with the reaction.

In one case of severe epilepsy in which seizures were temporarily under control as a result of the dehydration regimen, rehydration was repeatedly found to be accompanied by both a relative and an absolute increase in the excretion of potassium. A reversal of the urinary potassium to sodium ratio regularly appeared even before the seizures occurred. Pituitary antidiuresis accentuated this reaction, whereas luminal had an opposite effect.

While studies on the blood lipids revealed no clear-cut relationship between the occurrence of seizures and the absolute level of either cholsterol or lecithin, they definitely indicated that the lecithin to cholesterol ratio tends to be highest in samples taken nearest to the time of seizures. These data, together with the foregoing, were tentatively interpreted as suggesting that there is an inherent defect in the mechanism for controlling the permeability of the brain cell membranes in epilepsy. Therapeutic implications from such an interpretation were discussed. The circumstance that most of the conditions which favor the occurrence of seizures, such as alkalosis, anoxemia, superhydration and excitation, are likewise known to increase cell membrane permeability, and that factors which prevent them, such as sedation and narcosis, cause decrease in permeability, lends support to this general thesis.

DISCUSSION

Dr. E. M. Hammes (St. Paul): Doctor McQuarrie has presented this interesting experimental work on epilepsy in a most fascinating way. The more I hear about the theories on the etiologic factors in essential epilepsy, the more confused I become.

When Temple Fay brought forth his dehydration treatment, because of increased spinal fluid findings in epilepsy, we felt that at least an important mechanical factor had been solved in this very obscure problem. However, there are many clinical experiences which are difficult to explain on any of these theories. It is a well known fact that an epileptic will be free from convulsions for months and months following some surgical procedure, regardless of what or where the operation was, and then have a recurrence of his convulsions without any apparent cause. Reed of Cincinnati demonstrated that in a large number of epileptics, in whom he removed the colon without obtaining any permanent results.

Furthermore, epileptics frequently have a complete cessation of convulsions for months with or without treatment, and then suddenly develop a status epilepticus.

It is difficult to explain these facts with any theory that has been suggested. I would like to ask Doctor McQuarrie if his experimental work was limited solely to cases of grand mal, or if some studies have been made in cases where the convulsions were only of the petit mal type.

Dr. J. C. McKinley (Minneapolis): I should like to ask Dr. McQuarrie how far he would go in applying his ideas on the etiology of the so-called essential epilepsy to symptomatic epilepsy, that is to epilepsy secondary to tumors, meningeal inflammations, and things of that sort.

We are to be complimented in having such work as this going on in our community. Whether or not we agree that Dr. McQuarrie has uncovered the true etiologic factors is wholly aside from the question. He is showing us some phenomena of fundamental importance that are going on in our epileptics and is giving us at least a working hypothesis until sufficient facts can be accumulated to round out our conception of the disease.

Dr. McQuarrie (in closing): Petit mal cases do not seem to behave exactly like the others. So far we have confined our study chiefly to cases predominantly of the grand mal type. In the former a typical attack may occur while the nurse is out of the room for a moment and so may go unobserved, but if a patient has a grand mal seizure no doubt exists regarding its occurrence. I am under the impression that the mechanism is somewhat different in these two convulsive reactions. The patients upon whom the effects of the special therapeutic regimen were studied were chiefly those having many convulsions daily because it is from these alone that one is justified in drawing conclusions unless very long periods of observations are used. What occasionally occurs when a severely epileptic patient is placed upon a forced fluid regimen is a washing out of minerals with a resulting net loss in body water. This effect may be responsible for the decrease in the number of seizures. When water is stored under similar conditions convulsions are likely to recur.

It is true that in occasional instances patients stop having seizures after undergoing operative procedures of various sorts. On the other hand, if one expects such a result with any degree of frequency one is likely to be disappointed. The multiplicity of minor factors which apparently influence the course of this disease cannot be explained until more has been learned regarding its underlying pathological physiology. The permeability of the living cell membrane is not constant, but is known to vary in degree from time to time, probably in accordance with the state of nutrition of the cell, its oxygen supply, the PH of its environment, etc. It is possible that some of the minor provocative factors, such as fright or reflex irritation from certain pathological lesions, influence brain cell permeability in the direction favoring the occurrence of convulsions.

In regard to Dr. McKinley's discussion, he knows much more about that than I do, I am sure. I have no explanation of the fact that some persons have convulsions from head injuries. It is said that epilepsy developed in but 5.4 per cent of the cases of head injury during the war. Since the incidence of epilepsy in the general population is around 0.4 per cent there must be many more persons who have the characteristic underlying defect in their nervous makeup but who do not have convulsions until they have some brain injury. It is difficult to explain on any other ground the fact that a given circumscribed lesion, such as a brain tumor, abscess or traumatic scar, appears to cause seizures in but a minority of cases.

Dr. F. E. B. Foley (St. Paul) gave a lantern slide talk on "The Embryology and Surgical Correction of Certain Renal Malformations" and reported three cases of horseshoe kidney operated.

Dr. E. A. Boyden of the Department of Anatomy at the University of Minnesota discussed the embryological development of anomalies of the kidney.

The meeting adjourned.

R. T. LaVake, M.D., *Secretary.*

PROCEEDINGS OF THE MINNEAPOLIS SURGICAL SOCIETY

Meeting of January 7, 1932

The regular monthly meeting of the Minneapolis Surgical Society was held in the Lounge on the 30th floor of the Medical Arts Building on Thursday evening, January 7, 1932.

The meeting was called to order at 8 P. M. by the President, Dr. J. Frank Corbett. There were 31 members and 6 visitors present.

The following scientific program was presented.

Dr. E. A. Regnier reported a case of "Acute Pancreatitis Secondary to Common Duct Obstruction" as follows:

Mr. S. S., age 35, No. 8582, was admitted to General Hospital on surgery service on September 5, 1931, at 8:00 P. M. He complained of severe pain in the epigastrium, with nausea and vomiting. The patient was well until 8:30 A. M. on the day of his admittance. At 8:30 A. M., while cranking his car, he was suddenly seized with a severe pain in the epigastrium. He collapsed. The pain remained until 11:00 A. M., but eased up about this time. About one hour later the pain returned with increased severity and he vomited many times. He called a doctor, who gave him morphin and sent him to the hospital.

His past history is negative except for vague gastrointestinal distress during the past two years. He had had gallbladder studies a year ago in Chicago but was told that he had no gallbladder disease.

Physical examination reveals a very acutely ill patient. There was no jaundice; temperature 101.4°, pulse 116, respiration 34, blood pressure 124/72. The pupils were equal and regular. There was much dental caries. No abnormal adenopathy. Heart and lungs were normal. He showed boardlike rigidity over the entire abdomen. Palpation over any portion of the abdomen seemed to increase the pain in the epigastrium. There were no masses felt. Rectal examination was negative. W.B.C. 23,000. P.m.n.'s 93%. Urine negative.

Diagnostic impression: perforated ulcer, pancreatitis.

Operation: Under spinal anesthesia the abdomen was opened through the upper right rectus incision. There was a copious quantity of bile-stained fluid in the abdomen. The stomach and duodenum were normal. There were numerous areas of fat necrosis about the peritoneum and the mesenteries of the intestine. There was an extreme degree of edema of the pancreas and surrounding tissues. There was no hemorrhagic exudate. The gallbladder was tense and slightly thickened. There was a hard mass, palpable, in the region of the common bile duct. The duct was incised and several stones ranging from ½ to one cm. were removed. The stones were faceted. A "T" tube was inserted in the common duct for drainage. The gallbladder was opened and a great many stones were removed. The gallbladder was closed and left in place. A Penrose drain was inserted down into the foramen of Winslow.

Postoperative diagnosis: (1) common duct obstruction; (2) acute pancreatitis with fat necrosis; (3) gall stones; (4) chronic cholecystitis.

The immediate postoperative condition was quite stormy. The patient had typical postoperative asthenia as described by Whipple. He was given daily intravenous injections of glucose and after about ten days he began to improve quite readily. The "T" tube was removed the third week following the operation. The patient was discharged from the hospital on October 16, 1931, at which time the wound was practically healed. It is now four months since the operation and the patient has gained 35 pounds in weight.

Dr. Robert Schwyzer read his Inaugural Thesis, entitled "Pancreatitis, with Report of Cases."

ABSTRACT

A case of acute pancreatitis with fat necrosis and sanguinolent exudate in the peritoneal cavity is presented. It is interesting because its onset was not as stormy as usual and was not preceded by a history of gallbladder disease. The biliary system at operation was found to be normal. Simple drainage of the lower cavity was done and the patient recovered.

In the discussion of *etiology* the various factors, such as obstruction of the pancreatic duct, regurgitation of bile and extension through the lymphatics, are considered; laying stress on the fact that acute pancreatitis may follow many infections in the body, and especially epidemic parotitis.

The *symptomatology* is studied of 382 cases collected from the literature of the last ten years. Females prevail with 65 per cent. Biliary disease was present in 71 per cent, occlusion by stone in none. Pain was found constantly, mostly located in the epigastrium, postprandial in cases accompanied by gallbladder. Tenderness, pathognomic when localized in left hypochondrium, was absent in a few cases. Rigidity is never very marked. Vomiting occurs in nearly 100 per cent and is described as incessant. Cyanosis and shock, important in the differential diagnosis, were present only in about 40 per cent of the cases. The prognosis of these is bad. Icterus was found in 30 per cent. Pulse and temperature are variable. Kidney function is often impaired; glycosuria and hyperglycemia are rare.

Leukocyte count increased, relative increase of the polynuclear not characteristic. Increase of diastase in the blood is of no value, while increase of diastase in the urine to 250 units or more is of help in the differential diagnosis, but failures up to 20 per cent of cases have to be considered.

Pathology varies from edema to destruction of the gland. Fat necrosis is mostly present, the exudate in 72 per cent. This is primarily mostly sterile.

Complications: cyst, abscess, extension of fat necrosis to pleura, embolic abscesses of the liver.

Difficulty in exact differential diagnosis.

Extent of surgery depends on findings; biliary surgery only in light cases, in late cases drainage of gland.

Postoperative complications; arrosion of skin and fistula, hemorrhage.

Sequelæ: asthenia, diabetes, and chronic pancreatitis.

Recurrences: not uncommon, especially in cases complicated by gallstones.

Mortality: 55 per cent for all cases. Less in cases with edema of gland only, greater when necrosis is present. In exudate cases, prognosis worse.

Early operation treatment of choice despite publication of Mikkelson, only 7 out of his 50 cases proven by biopsy or autopsy.

Comment: Prevention is increased by early biliary surgery. Cases operated on early give better prognosis. Limited surgery indicated in cases with peritonitis. Intervention preferable to conservatism.

Dr. O. H. Wangensteen gave a paper on "Acute Pancreatic Necrosis with Comments on Diagnosis and Therapy" (to be published elsewhere).

ABSTRACT

Dr. Wangensteen stated that he would like to preface his remarks by stating that no one is infallible in the differential diagnosis of acute disasters of the abdomen. It was his impression, until some years ago, that acute pancreatitis was heralded by the appearance of shock, a rapid pulse, and cyanosis. Six years ago he saw his first clinical case of acute pancreatic necrosis. It concerned a woman aged 39, the mother of four children. She complained of diffuse severe abdominal pain and gave a history of several attacks of upper right quadrant pain that seemed to be best interpreted as attacks of gallbladder disease. The pulse in this attack was 90, the temperature 100.4° F., and the blood pressure was normal. The pain was severe, but the patient did not look especially ill. On examination of the abdomen, tenderness and rigidity about 2+ were found to be present everywhere. There was no greater rigidity in the region of the gallbladder than elsewhere. Rectal and pelvic examination was negative. A diagnosis of acute cholecystitis (probably empyema) with threatening inundation of the peritoneal cavity was made, though this diagnosis was not satisfactory in the absence of greater rigidity over the upper rectus muscle. At operation, performed under a combination of local infiltration and nitrous oxide anesthesia, the correct diagnosis of acute pancreatic necrosis was established on entry of the peritoneal cavity by the presence of fat necrosis and an abundant brownish sanguinous fluid. The peritoneal cavity was drained, as was the gallbladder, several gall stones being simultaneously removed. The pancreas was found to be soft and fiery red; its capsule was split and large gauze tampons were led down to the pancreas through both the gastro-hepatic and gastro-colic ligaments. The next morning the patient's condition was fair, though the blood pressure was somewhat depressed and slight cyanosis of the finger tips was present. About sixteen hours after operation she presented the classical text-book picture of acute pancreatitis. She was deeply cyanosed and shock was extreme. There was blood in the vomitus and in the urine. Necropsy examination showed hemorrhages in the intestinal canal, the lungs, kidneys, and other tissues. Undoubtedly there was trypsin in the blood stream.

About a year later, another patient, presenting the same picture as detailed in the above case record, was seen. There was but slight elevation of the pulse, and moderate temperature rise. The patient complained of severe abdominal pain and physical examination revealed diffuse abdominal tenderness and rigidity of about 2+ to 3. A diagnosis of acute pancreatic necrosis was made and confirmed at operation. The same operative procedure was performed as in the first case, with the same outcome.

To date, four patients, Dr. Wangensteen stated, have been operated upon with the same outcome in each instance. Two of these survived for as long as sixteen days.

In April, 1931, a woman, aged 33, was observed at the University Hospital presenting the picture outlined above. A diagnosis of acute pancreatic necrosis was made and conservative therapy carried out. Somewhat more than three weeks later, at which time all of the abdominal symptoms had subsided and the patient was ambulant and eating well again, exploration was done. Many areas of fat necrosis as large as the thumb nail were still scattered throughout the upper abdomen. The gallbladder contained numerous stones and was excised. The patient convalesced uneventfully and has remained well. The instance of an adult male was then related in which a diagnosis of acute pancreatic necrosis was also made and delayed operation performed about a month later. Scattered areas of fat necrosis were still present throughout the mesenteries and a small mass was palpable in the mid-portion of the pancreas. The gallbladder was excised; it contained no stones, but a microscopic diagnosis of cholesterosis was made by the pathologist. The patient had a smooth convalescence and has remained well.

The conditions that must be differentiated from acute pancreatic necrosis, Dr. Wangensteen stated, were (1) acute appendicitis with peritonitis, (2) twisted ovarian cyst, (3) acute bowel obstruction, especially strangulation types of obstruction, (4) acute lesions of the gallbladder, (5) perforation of a duodenal or gastric ulcer.

Perforation of a hollow viscus in the upper reaches of the intestinal canal, Dr. Wangensteen went on, are heralded by a board-like rigidity of the abdomen. There is usually, however, no shock in the true sense for the pulse and blood pressure are usually normal despite the apparent prostration of the patient. The sudden onset and collapse of the patient may be very much the same in both conditions, but the rigidity is much greater in perforation, and gas can always be visualized beneath the diaphragm on the fluoroscopic table when the patient is brought into the erect posture.

The differential diagnosis of acute gallbladder lesions and pancreatitis was brought out above in recitation of the case histories.

Dr. Wangensteen said that most of the cases of acute pancreatic necrosis seen by him had been diagnosed acute intestinal obstruction because of the intense vomiting. The only varieties of bowel obstruction that would come into consideration are those types presenting tenderness, viz: the strangulation obstructions. Dr. Wangensteen felt that the recognition of acute bowel obstruction was one of the simplest of abdominal diagnoses. The concomitant occurrence of intermittent crampy pain at the acme of which loud borborygmi are heard with the stethoscope establishes the presence of intestinal colic. In pancreatic necrosis the abdomen is ominously silent on auscultation.

In twisted ovarian cyst, the pelvic findings usually predominate; in the cases of acute pancreatic necrosis observed by Dr. Wangensteen, the rectal and pelvic findings have been uniformly negative.

Acute appendicitis may be confused with almost any acute disorder of the abdomen. The onset is usually not as abrupt as in pancreatitis. Patients with appendicitis presenting diffuse abdominal rigidity are usually manifestly ill and the pulse would be found to be 120 and not 90 or less, as in most instances of acute pancreatic necrosis. Greater rigidity is usually present over the appendix and there is definite tenderness on rectal or vaginal examination.

With reference to treatment, Dr. Wangensteen said, the first case of acute pancreatic necrosis was successfully operated upon in 1890 by the late Halsted of Baltimore. He merely noted the findings, established the diagnosis and closed the abdomen. About ten years later, Hahn of the Friedrichshain hospital in Berlin operated successfully upon a second case. He drained the peritoneal cavity and attributed the recovery of the patient to this measure. In 1901, Halsted operated unsuccessfully upon the case in which Opie found a small stone impacted at the ampulla of Vater, which case has been the starting point of considerable investigative work relating to acute pancreatic necrosis. Whipple and a number of other investigators have since shown that the fluid in the peritoneal cavity is innocuous in pancreatitis and need not be drained off. In 1909, V. Haberer advocated routine drainage of the gall bladder in case of acute pancreatitis on the supposition that a block was present in the ampulla in most cases, the cholecystostomy serving as a drainage vent. A number of statistical studies have adequately shown that in only about 4 per cent of instances is a stone present in the ampulla; in about 14 per cent common duct stones are present. The generally accepted orthodox procedure in dealing with acute pancreatitis surgically is to place a gauze tampon down to the pancreas to permit the escape of the active ferment, trypsin.

It is readily apparent that there is no specific help in any of these types of procedure done at operation. Patients with acute pancreatic necrosis die of tryptic digestion of the pancreas. Trypsinogen is activated within the pancreas instead of by the physiologic activator, succus entericus, within the bowel. Splitting the pancreatic capsule or placing a tampon down to the pancreas would not appear to influence appreciably the process in the pancreas for recovery. Most instances of acute pancreatitis are a chemical digestion and not inflammatory in nature. Our therapeutic measures would appear to be better directed toward stopping the activation of trypsinogen within the gland itself. True enough, very little is known about the method of approach to the problem, but investigations along this line promise to be more productive of results than operation that accomplishes nothing specific.

Only in those instances in which jaundice is present or when the diagnosis remains in doubt should operation be performed. It is to be recalled that Halsted failed to find the stone at the ampulla in his case, now famous through the report of Opie, despite the fact that he opened and probed a dilated common duct. He frankly stated that he believed that he shortened the patient's life by operating.

If there be any common denominator of acute pancreatic necrosis it is gall stones or chronic disease of the gallbladder, one of these conditions being present in about 70 per cent of instances of acute pancreatitis. Dr. Wangensteen believed therefore that it was wise in most instances to do a delayed operation and to excise the gallbladder. The manner in which gallbladder disease predisposes to acute pancreatic necrosis is not well understood. Experimental acute biliary infections do not give rise to acute pancreatitis. Certainly our universally practiced method of treating acute cholecystitis conservatively should eventuate in a number of cases of acute pancreatitis if acute biliary infections were a precursor of pancreatic necrosis. The safety of treating acute biliary infections conservatively is well established. It was Dr. Wangensteen's impression that the cause of most instances of acute pancreatic necrosis was to be sought in a combination of factors which, when operating singly, were unable to produce the disease.

That the diagnosis of acute pancreatic necrosis can be made with some assurance without operation, Dr. Wangensteen felt to be well demonstrated in this small series in that every case was recognized, with the exception of the first. Dr. Wangensteen stated that only once had the diagnosis of acute pancreatic necrosis been made when the operative findings were negative. This patient complained of severe left sided pain, a sign to which Katsch of V. Bergmann's clinic has called attention as being of diagnostic import in acute pancreatitis. This patient later developed a frank pneumonia and Dr. Wangensteen felt that the abdominal pain was due to a diaphragmatic pleurisy. Dr. Wangensteen stated that none of the cases in his series complained of localized left sided abdominal pain. Dr. Wangensteen stated that he had no experience with the urinary diastase test of Wohlgemuth nor with the blood anylase test of Elman of St. Louis. He felt that these were not specific in that abdominal findings have been recorded in other conditions.

Dr. Wangensteen wished to stress the point that the usual symptomatology of acute pancreatic necrosis is more like that described here than that found in texts. The textbook description obtains usually only antemortum or in instances of "pancreatic apoplexy."

The operative mortality in dealing with acute pancreatic necrosis is more than 50 per cent, as shown by a number of statistical studies. Dr. Wangensteen felt if a patient might survive operation which accomplishes nothing specific for sixteen days that without operation the patient's chances were very much improved. There will naturally be deaths with conservative treatment, but Dr. Wangensteen felt that they would be less numerous. Practically all patients with "pancreatic apoplexy" in which large blood vessels are eroded die very quickly and dramatically with the typical picture of profound shock.

Starvation, Dr. Wangensteen felt, was to be an important item in the treatment because it inhibited in some degree the secretion of more tryptic ferment. Massive hot packs should be applied to the entire abdomen, and whatever narcotics are necessary to allay pain should be given. The vomiting of which these patients complain and the gaseous distention of the bowels are allayed by continuous nasal catheter suction siphonage, a measure that D. Wangensteen has found of great value in combating postoperative distention. The chief source of gas in the bowel is swallowed air, Dr. Wangensteen stated, and if the oral source is cut off, the distention will abate. Dr. Wangensteen said that he had treated four cases of simple mechanical bowel obstruction successfully without operation by this method. Enough fluid should be given by para-oral routes to insure a good urine output.

DISCUSSIONS (on pancreatitis)

Dr. J. F. Corbett stated that a condition which cannot be recognized clinically at all in many cases, and a condition that varies so much in its essential pathology, is going to add difficulties to the problem that confronts surgeons; but what he wanted to know was whether to operate or not to operate in these cases. He wished to compliment both the essayists and thought that a full discussion of the subject might aid materially in clearing up this subject.

In regard to Dr. Regnier's question in his case, Dr. Corbett felt that the answer would be determined by the kind of insurance; if this comes under compensation, he felt that the man would be entitled to collect; but if it comes under the ordinary accident policy, he felt the man could not collect because most accident policies say that the cause of death must be solely and alone due to the accident. He was of the opinion that in this case the policy is of fundamental importance.

Dr. T. H. Sweetser, as evidence in considering the advisability of delayed operations, called attention to three cases which had been under his father's care and with which he too was familiar. One patient, a victim of repeated gall stone colic, was brought to the hospital critically ill with signs of cholecystitis and acute pancreatitis. Operation was delayed for 14 days, after which the gallbladder was removed and the patient recovered. At operation the diagnosis was confirmed. The other two patients presented a complication which has not been emphasized this evening. The first of these came to them two months after the onset of acute pancreatitis. A pseudo-cyst of the pancreas was present when the patient arrived and at operation was found to contain 2,000 c.c. of fluid. In spite of drainage the pancreatic necrosis evidently spread gradually so that he died about two months later. At autopsy no remnant of living pancreatic tissue could be found. The second patient came complaining of abdominal distress and vomiting about four and a half months after a cholecystectomy for gall stones; it is reported that at that operation the surgeon had noticed patches of fat necrosis and enlargement of the pancreas. When she came to them a tumor could be demonstrated, which was proved to be a pseudo-cyst of the pancreas. The patient fully recovered following drainage of the pseudo-cyst.

Dr. Willard White was of the opinion that there are a number of things about this subject that are not understood, and he also believed that it was apparent that there are different factors that enter into the etiology in different cases. In Dr. Schwyzer's report there were 11 of his series that complicated disease of the tubes. It is difficult to explain the occurrence of pancreatitis with salpingitis; but most likely it would be either through the circulation or the lymphatic system.

Dr. White said that his own idea of why it is justifiable to operate on some of these cases of acute pancreatitis is based on his assumption that acute pancreatitis is due to the direct extension of disease in the bile passages and not necessarily by regurgitation of bile into the pancreatic duct. There are some factors which cause inflammation of the duct. The common duct of course passes through the head of the pancreas, and inflammation may extend into the pancreas by different extension and result in inflammation of the pancreas.

He cited one case of his own. The patient was a woman somewhere between 40 and 50 years of age, who entered the General Hospital with a picture of an acute and severe illness, with tenderness and pain located in the upper abdomen, and with a great deal of vomiting. He watched her for a while and was afraid not to operate. At operation he found a swelling of the pancreas. He drained the common duct, inserted forceps in the swollen area and she recovered.

He said he was greatly interested in hearing the other side of the question, that one should not operate on these cases.

Dr. E. A. Regnier said he was interested in Dr. Wangensteen's remarks and observation of this disease. He was of the opinion that the cases reported by Dr. Wangensteen were not all of fulminating type. He believed that a great many cases are of sub-acute type and that many of them would recover without operations. Cases of pancreatitis have been reported in children three or four years of age without any disease of the biliary tract but because of the high incidence of biliary disease associated with pancreatitis he had been led to assume that the two must be related. In the case Dr. Regnier reported he said he had diagnosed perforated ulcer first, and pancreatitis second, because of the absolute board-like rigidity of the abdomen, the absence of jaundice and the normal blood pressure. This patient appeared to be in shock, but his blood pressure was 124/72. Dr. Regnier did not believe that any surgeon would have dared refrain from doing a laparotomy on this patient. He felt that a fairly large per cent of these patients present symptoms that call for immediate operations. So far as treatment is concerned, Dr. Regnier did not see any good in incising the pancreas, but felt that the biliary tract should be drained when it was evident there was obstruction.

Dr. E. C. Robitshek said, in view of his limited experience in cases of acute pancreatitis, he hesitated to enter into the discussion. He had seen only two cases (both acute hemorrhagic in type) which he felt should be treated surgically. He followed the views of Sir Berkeley Moynihan, who divided the disease according to the classification suggested by Fitz, namely, of three types, the hemorrhagic, gangrenous and suppurative.

As to the symptoms, Dr. Robitshek desired to repeat, and emphasize, what had already been mentioned. First, pain. Pain, and not vomiting, shock, or cyanosis, is the first and most important symptom. According to Moynihan, "of all the pains the human body can suffer, this is by far the worst." Morphine gives little or no relief. Dr. Robitshek remembered distinctly the last case of acute pancreatitis he operated—a woman, who, in spite of a half grain of morphin sulphate, administered hypodermically at her home, shrieked with pain from the onset of the attack until placed under the anesthetic on the operating table. Among other important phases of pain, in these cases, are such as the pain being very sudden, and violent in onset, not infrequently following a hearty, heavy meal, most severe in the epigastrium, and radiating to the back or loins.

Second, vomiting. This is almost constantly present, occurs early, is severe, recurs frequently, and resembles the vomiting of high bowel obstruction.

Third, shock. This must be understood to mean a rapid, weak pulse, cold face and extremities, shallow respiration, pallor and low blood pressure, and not merely prostration and anguish of pain. Here again Moynihan says, "Of the existence of shock in acute pancreatitis there is never the slightest doubt. No such state is seen in any other abdominal calamity."

Fourth, cyanosis or livid spots. Halsted was the first to call attention to this sign, as seen on the face, or in irregular patches on the abdomen (frequently about the umbilicus), on the limbs or about the loins. Such patches when present in an acuate abdominal condition might be considered almost pathognomonic of pancreatitis.

Fifth, rigidity and tenderness. These are both present over the abdomen, but more especially over the epigastric region, yet not so marked as the board-like rigidity or marked abdominal tenderness seen in cases of perforated peptic ulcers.

Just a word about differential diagnosis; most of these cases Dr. Robitshek thought resembled, clinically, perforated peptic ulcers. It is well to remember, however, that acute pancreatitis occurs more frequently in females, whereas acute perforated peptic ulcers occur almost 100 to 1 times more frequently in males.

Dr. Robitshek said he had little or no faith in the Löwe test or in the Cammidge reaction, in cases of acute pancreatitis.

Dr. J. M. Hayes said he had enjoyed this discussion very much and felt that he had learned something from it. He said his experience with this condition was much the same as that of Dr. Robitshek. He had not seen the type mentioned by Dr. Wangensteen. Perhaps it was because they had not been diagnosed as early as those Dr. Wangensteen reports. He had explored just two cases and they both were extreme cases. The only reason for exploring them was that the diagnosis might not have been correct. Both of these cases reminded him of the description of Sir Berkeley Moynihan's cases. He says, when one sees the *facies* of one of these patients once he never forgets it. The patient is in extreme agony. The pain is almost impossible to relieve.

The first patient had been seen by another doctor and a diagnosis of cholecystitis made. He gave the patient a hypodermic of morphin, and was not called back to see him for twenty-four or thirty-six hours. When the doctor returned the patient was in extreme pain. Three-quarters of a grain of morphin had little effect on the pain. The patient was taken to the hospital at once. "Board-like" rigidity was present over the abdomen. The patient gave the picture of shock. He was explored immediately, a brownish fluid escaped and extensive fat necrosis was present. The abdomen was closed at once and the patient died a few hours later.

The second case was a patient brought in from the country. While climbing up on a load of hay he was suddenly seized with abdominal pain. He got down and went to the house and as soon as he reached the house he collapsed. When he reached the hospital, after a long ride through the country, his abdomen was "board-like" and he was in extreme shock. Again the only hope from an exploration was the possibility of an incorrect diagnosis.

He said he was very glad to listen to this report of these cases by Dr. Wangensteen. He had not observed this type of case, although he had seen such cases reported. He agreed with Dr. Wangensteen that very little could be expected from operation if one was absolutely sure of the diagnosis.

Dr. Corbett stated that he had had a few cases of pancreatitis. One of them he thought was gallbladder and he continued to think it was gallbladder as it went through much the same course that any gallbladder case does. Finally, an X-ray of the stomach showed a bit-out piece, and he then knew there was a cyst. He opened that case and apparently the whole pancreas came out. He brought the pseudo-cyst out and marsupialized it and that man recovered. The next case was a man who had rather indefinite symptoms and X-ray showed much the same picture, but unfortunately before the patient had got onto the operating table the cyst burst and was fatal. The next case was one of the most fulminating Dr. Corbett had ever seen. The woman seemed to have two distinct cycles of symptoms. The first was this semi-rigidity of the abdomen, perhaps a little more on one side than on the other, probably a 2+ rigidity. Then Dr. Corbett was in doubt as to the diagnosis. Pictures were taken for gas. These particular pictures were not clear and some more had to be taken. Very quickly the fulminating symptoms came on after that. Then the whole abdomen became rigid and board-like and had the appearance of a perforated ulcer. He operated and found a suppurated pancreatitis with peritonitis, and he lost that case also. The pancreas in that case seemed almost in the process of suppuration; it was a mass of suppurating tissue.

Dr. Corbett said it seemed to him that statistics were pretty doubtful unless one discriminates between cases, *i.e.*, between the fulminating and the slow cases. When one sees a mild case he thinks he might wait, but when he sees a case go back on him, he may think that if he had hurried a little the patient might have been saved.

Dr. H. O. McPheeters said he would like to ask one question, and that was in regard to coronary thrombosis in the differential diagnosis of these cases. In the milder cases and not the fulminating type, may not the pain be confused with that of coronary thrombosis when the latter is not typical?

Dr. Robert Schwyzer thought that coronary sclerosis has to be considered in these cases. There is also another condition of the abdomen that must be considered in the differential diagnosis and that is thrombosis or embolism of the mesenteric vessels. In this, the pain may be about the same as in pancreatitis.

Dr. Wangensteen stated that he was not a proponent of the idea of operating on acute gallbladders. It is true, he said, that surgeons who have made a practice of operating for acute cholecystitis have occasionally seen scattered areas of fat necrosis at operation. Zoeppfel of the Barmbeck Krankenhaus reported seeing ten such instances among 150 cases of acute cholecystitis operated upon in the acute stage. Zoeppel has described this condition as a "Vorstufe" or prestadium of acute pancreatic necrosis. Whereas there were no deaths in the ten cases seen by Zoeppel or in another small group by Arnsberger, the mortality of acute pancreatic necrosis is more than fifty per cent. Dr. Wangensteen felt definitely that these were not the same disease. If this pancreatic edema with scattered fat necrosis observed occasionally at operation in acute cholecystitis were a forerunner of actual pancreatic necrosis, Dr. Wangensteen believed that many deaths from acute pancreatitis should be observed as a natural complication of our conservative treatment of acute cholecystitis. On the contrary, acute pancreatic necrosis is rarely observed as a complication of acute biliary disease, but chronic disease of the biliary tract in some manner predisposes to acute pancreatitis. Dr. Wangensteen related here that when he and his associates had established a common channel of common bile and pancreatic ducts by placing a ligature at the ampulla in cats, pancreatic necrosis did not result. When, however, this was done and a gastrostomy was made and a fatty meal of milk and cream and bile salts fed, pancreatitis resulted in a large number of instances. Excision of the gallbladder diminished the likelihood to the development of pancreatitis after a fatty meal. The feeding of alcohol, carbohydrates, or protein food through the gastrostomy tube in the presence of the common channel did not produce acute pancreatitis.

Even though the case records recited had impressed Dr. Regnier as being rather mild forms of the disease, Dr. Wangensteen submitted that, inasmuch as all the cases that he had operated upon acutely had died, he felt that this distinction was not well founded. Dr. Wangensteen believed that the picture he described was of more frequent occurrence than the textbook description of shock and cyanosis. Actual shock rarely attends acute abdominal disasters, Dr. Wangensteen stated, unless there had been considerable bleeding. Rupture of solid viscera such as the spleen or liver with ensuant hemorrhage is frequently followed by shock. Dr. Wangensteen stated that he had never seen shock soon after perforation of a hollow viscus, such as a perforated duodenal ulcer. True enough, the patient may be severely prostated, but actual shock, as manifested by a rapid thready pulse or a depressed arterial blood pressure, is not present. Similarly, in acute pancreatic necrosis, Dr. Wangensteen felt that there would be true shock early only when "pancreatic apoplexy" is present. The prostration, however, may be marked. A number of ill-defined conditions are grouped together under the caption of shock, but clinicians should limit its use to a description of conditions in which the pulse is hurried and a marked depression of the arterial blood pressure is present.

Dr. Wangensteen stated in answer to the inquiry that, should he encounter acute pancreatic necrosis at operation, he would close the abdomen, unless the common duct were dilated, in which event he would drain the gallbladder. He believed that a perforated ulcer could be differentiated from pancreatic necrosis in all instances by the aid of the fluoroscope. In only one instance in this group of cases, Dr. Wangensteen stated, was the rigidity great enough to suggest a perforated duodenal ulcer. No air was visualized beneath the diaphragm. Some years ago, Dr. Wangensteen stated that he had closed by suture the perforation of a duodenal ulcer for a student. A year ago, the patient presented himself again with signs of a perforation, but no gas was visualized beneath the diaphragm on fluoroscopy and on plates taken in the erect posture; and it was therefore felt that a tag of omentum had sealed the perforation and no further leakage was occurring. The patient did well on conservative observation.

The delayed operation should be done for acute pancreatitis, Dr. Wangensteen believed, for the majority had gallbladder disease. In young patients (under 20) perhaps the same indication for the performance of operation did not exist, as it would be less likely that coexistent biliary disease would be found. Recurrent acute pancreatic necrosis may also occur, and even after excision of the gallbladder, but less frequently than if the biliary tract disease remains uncorrected.

Wohlgemuth believed the best diet in acute pancreatitis to be an anti-diabetic regime with high fat and protein content. Dr. Wangensteen felt on the contrary that fat was to be avoided because of the relationship of pancreatitis to fatty meals as shown in the experiments referred to above. Camus and Gley maintained that they had produced active trypsin in the pancreas by electrical vagus stimulation. As a corollary of this, Dr. Wangensteen felt that it might be advantageous to give atropin in the attempt to inhibit pancreatic secretion.

Dr. Corbett said he had enjoyed this program very much and he wanted to thank the men for the pleasure it had given him and he was sure the other members were of the same opinion.

Dr. T. H. Sweetser reported the following "Unusual Case of Adenomatous Prostate."

This case is reported to call your attention to the pathological and surgical importance of a small group of "accessory" gland tubules at the bladder outlet, the subcervical glands of Albarran. This group is barely mentioned in texts on urology and in some anatomies, but has been discussed occasionally in the periodicals and recently in a monograph on the surgical pathology of prostatic obstruction.

The patient, a man 77 years old, was brought to the hospital in critical condition during the subsidence of a protracted severe urinary hemorrhage. His urine was extremely foul due to the fact that he had catheterized himself for the past eight years without any attempt at aseptic technic. An inlying urethral catheter was not well tolerated. Therefore a prevesical incision was made down to the bladder wall, the wound was packed open, and on the third day the bladder was opened. Both stages were done under local infiltration anesthesia with as little insult as possible, but his blood pressure dropped and continued low. He died ten days after admission from circulatory failure and terminal bronchopneumonia.

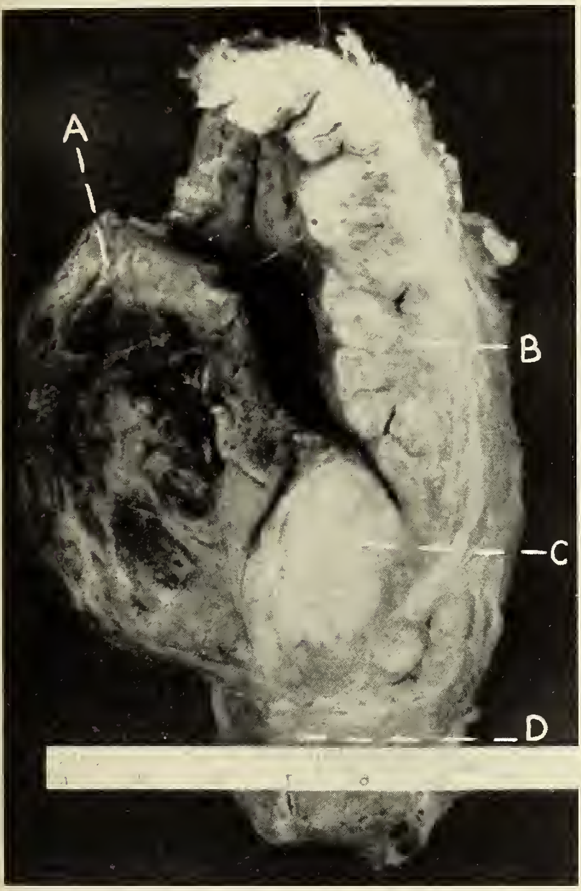

Fig. 1. Sagittal section through bladder, prostate, and pedunculated tumor. *A*, pedunculated tumor from Albarran's glands; *B*, bladder wall, mucosa greatly thickened; *C*, middle lobe of prostate; *D*, lateral lobe of prostate.

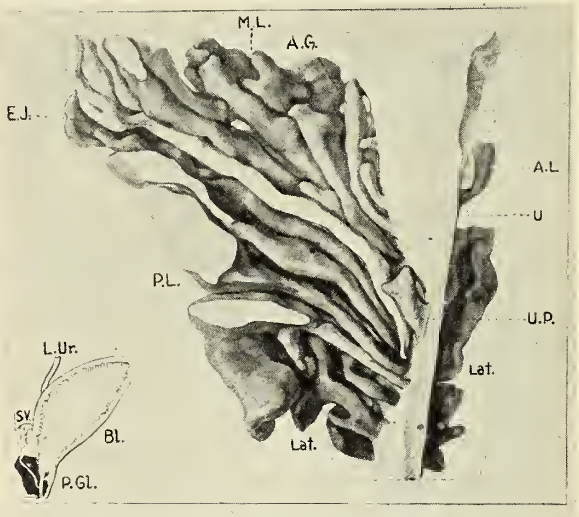
Autopsy showed a remarkable condition. True, there was found a moderate enlargement of both lateral lobes of the prostate and also of the middle lobe or commissural portion. But in addition there was a large soft hemorrhagic solid round mass almost filling the bladder and attached by a pedicle to the floor of the prostatic urethra proximal to the verumontanum. This mass was evidently an adenomatous enlargement originating in Albarran's group of subcervical gland tubules. The bladder wall was very thick, due quite largely to hyperemia and inflammatory edema of the mucosa. The pedunculated mass was the evident source of the hemorrhage and toxemia, as well as the principal cause of the urinary obstruction, forming a fairly perfect ball valve.

The illustration, a sagittal section, shows well the characteristics of enlargements originating in the middle lobe or commissural tubules of the prostate, and the characteristics of enlargements originating in Albarran's group of subcervical gland tubules.

According to Lowsley's description,[1] the prostate itself develops from five groups of tubules, anterior, posterior, middle, and two lateral, which in early embryonic life are separate, but which later coalesce to form a single organ. Separately, in the submucosa of the prostatic urethra, just at and distal to the bladder outlet, a group of tubules appear about the sixteenth week of fetal life, the so-called Albarran's subcervical glands. They are separate from the prostate, of somewhat different structure microscopically, and may enlarge independently without prostatic hypertrophy.



Sagittal view of a wax model of the prostate of a new-born infant. × 14. *Lat.*, anterior tubes of lateral lobes; *P.L.*, posterior lobe; *E.J.*, ejaculatory duct; *S.V.*, seminal vesicle; *A.L.*, anterior lobe tubule; *U.*, urethra; *U.P.*, utriculus prostaticus; *A.G.*, subcervical glands of Albarran; *M.L.*, middle lobe tubules; *L.Ur.*, left ureter; *Bl.*, bladder; *P.Gl.*, prostate gland.

Fig. 2. Reduction from illustration in article by Lowsley,[1] Journal of Anatomy, 1912.

Alexander Randall has well described the differences in the effect of enlargement of these various structures.[2, 3] The middle lobe of the prostate, being situated underneath the trigone muscles, pushes upward under them and projects into the bladder as a sessile rounded mass in the midline. Albarran's glands, being situated in the submucosa overlying the muscle bundles that extend from the trigone into the prostatic urethra, enlarge directly out into the urethra and thence upward into the bladder. Being restrained by no overlying muscle, such an enlargement is globular and soon becomes pedunculated and lies within the bladder attached by a pedicle to the floor of the urethra.

Diagnosis may be made by cystoscopy, but a marked enlargement originating in Albarran's glands may be confusing if one does not keep that entity in mind.

Surgically, it is readily seen that, while the enlarged prostatic middle lobe may be removed in one mass with the enlarged lateral lobes either suprapubically or through the perineum, the removal of a greatly enlarged pedunculated subcervical gland mass is quite a different matter. Such a mass may easily be removed through a suprapubic opening by division of its pedicle; enucleation of any prostatic enlargement that may be found would then be an independent step in the operation. During a perineal prostatectomy, on the other hand, an enlargement of Albarran's glands may easily be missed entirely, especially if large and pedunculated as in this case; the operation will then fail to give relief. With the enlargement of such a size as seen here it would seem to me that, even though recognized preoperatively, satisfactory removal perineally would be impossible; only a suprapubic approach would be adequate.

DISCUSSION

DR. O. H. WANGENSTEEN asked Dr. Sweetser if it is not true that Zuckerkandl and Tardler, in their monograph on hypertrophy of the prostate, state that prostatic hypertrophy of the prostate itself is due to the growth of the paraurethral glands into it.

The meeting adjourned.

Secretary.

INJECTABLE OVARIAN PREPARATIONS OMITTED FROM N. N. R.

In 1930, the Council on Pharmacy and Chemistry omitted all desiccated ovarian preparations for oral administration, provisionally retaining those intended for intramuscular or hypodermic administration. The manufacturers of these products were informed that these would be omitted at the close of 1931, unless meanwhile acceptable methods of assay for hormone content were adopted and acceptable evidence for their effectiveness, submitted. The interested firms have not submitted such evidence. As to the adoption of an assay method, it was later decided, on the basis of opinions expressed by the Council's consultants that our present knowledge make it undesirable to adopt assay methods for the determinaton of the hormone content of these water-soluble preparations. Since no acceptable evidence exists for the usefulness of such preparations, the Council voted to omit Ovarian Substance Soluble Extract—P. D. & Co.; Corpora Lutea Soluble Extract—P. D. & Co.; Corpus Luteum Extract-Lederle, Corpora Lutea Soluble Extract—Wilson, and Sterile Solution of Lutein—H. W. & D. (Jour. A. M. A., January 30, 1932, p. 402.)

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

EXTRACTS FROM THE PROCEEDINGS OF THE SIXTH CONGRESS OF OTO-LARYNGOLOGY OF THE COUNTRIES OF THE NORTH. (Acta Oto-Laryngologica, Vol. XVI.)

Frithiof Leegaard (Oslo), *The Treatment of Inflammation in the Nasal Sinuses.*

The author and a large number of those who discuss his paper, voice their experiences particularly in regard to: (1) radical sinus surgery with complete removal of the membrane or partial removal, (2) the problem of adequate treatment in chronic frontal sinus infections.

Leegaard reports excellent results in chronic maxillary infection with a compromise between the radical method of the Caldwell-Luc operation and the making of an ordinary sinus window. He makes an unusually large opening in the inferior meatus, and then removes the tip of the overlying inferior turbinate. He believes that the removal of the anterior tip is an important factor in his successes. This procedure suffices for the majority of causes and only rarely does the author resort to the Caldwell-Luc operation.

The consensus of opinion seems to be that as good if not better results are obtained by removal of only diseased antrum lining as are obtained by a complete curetting or stripping out of the membrane.

Frontal sinus surgery after the method of Barany has several enthusiastic supporters. The author offers twenty-nine case reports. The method includes removal of the floor through an orbital approach. A large opening is made into the nose, the frontal process of the maxilla is removed completely to the pyriform aperture and also a portion of the nasal bone. A flap of nasal mucous membrane is then taken from the lateral nasal wall or the septum and swung up to line the passageway from the sinus to the nose. Paraffin gauze is used to tampon the passageway for the next 5 or 6 days. The sinus is then flushed once daily with sterile salt solution until healed. Only the diseased portion of the sinus membrane is, as a rule, removed.

F. Soderberg (Upsala) *About the Results of Barany's External Operation of the Frontal Sinuses.*

The Barany method of frontal sinus operation has been used in the Otological Clinic in Upsala for seven years. For this report the cases were re-examined to determine the end results. Forty-one cases constitute the group. Thirty-seven showed an adequate open communication between the sinus and nasal fossæ. In thirty-one of these cases the sinus membrane was left. Two of the cases died following operation.

S. Mygind (Copenhagen) *Treatment of Otogenic Sepsis and Sinus Thrombosis.* (Report from the Copenhagen Commune Hospital.)

In a period of eight years (1915-1922), 1000 mastoidectomies were performed. In this series there were ninety-eight cases of sinus thrombosis. The treatment of this complication consisted of jugular ligation and removal of thrombi. The mortality of cases so treated was 45 per cent.

In the eight years (1923-1930) following the completion of this first series, about 2,000 mastoidectomies were performed. The incidence of sinus thrombosis in this group amounted to 101. In treating this complication in this series, a conservative plan was followed. In only eight of the cases was jugular ligation thrombectomy done (six of the eight cases succumbed). The mortality was only 29 per cent.

Discussing these results, the author emphasizes the fact that series of statistics are difficult to compare properly. In institutions, cases are often admitted late; the type of infection prevalent, the incidence of brain abscess, and the proportion of acute to chronic infections all play a part in influencing the mortality rate. He believes, however, that in spite of the probability that they were better able to treat their cases in the second series because of added experience, and also the indication that the second series may have included less severe infections, conservative treatment results in a higher percentage of cures. The incidence of complication in the first series was ninety-eight cases of sinus thrombosis and twenty-seven of brain abscess to 1,000 mastoidectomies, while in the second series there were 101 cases of sinus thrombosis and 26 cases of brain abscess to 2,000 mastoidectomies.

Mygind concludes that any operation on the sinus or the jugular vein carries with it, because of the trauma, a certain added factor of risk. This is the result of: (1) the necessity of a new clot forming which probably becomes infected, (2) an interruption of the circulation which must be of consequence to the brain, meninges, and the power of resistance of the venous walls, and (3) the direct trauma of operation on the sinus, accompanied by the plugging.

Lawrence R. Boies, M.D.

GYNECOLOGY AND OBSTETRICS

THE DIAGNOSIS OF PREGNANCY BY THE BROUHA-HINGLAIS-SIMONNET REACTION: L. Brouha and H. Hinglais. (Gynecologie et Obstetrique, Tome XXIV, No. 1). This test is based upon the fact that the urine of pregnant women contains a specific hormone, and when samples of this urine are injected into immature male mice, puberty is brought about within a few days. This is determined by a rapid increase in the weight of the animal and especially by an increase in the size of the seminal vesicles.

Puberty in these animals normally occurs during the fifth or sixth week and is characterized by a definite increase in weight. For the test one should use mice of a known age, or weighing less than 10 grams. Samples of urine from 142 normal non-pregnant women were inject into 310 mice. In no instance was there any evidence of the specific hormonal reaction as shown by the characteristic changes. Samples of urine from thirty-seven non-pregnant women who were being treated in the clinic were injected, with no reaction which would suggest the presence of a specific hormone. Samples of urine from seventy-two pregnant women were injected into 291 mice. All of these showed characteristic reactions, namely an increase in the size of the seminal vesicle amounting to ten times that of the controls.

The urine is treated with ether and filtered as in the Zondek test. Increasing the dose does not hasten the reaction. Three injections of 0.3 c.c. a day for four days. Changes begin to appear in forty-eight hours and are characteristic by eight to ten days.

Up to date, tests from the urine of 400 pregnant women gave uniformly positive results, except in one instance through technical error. In the absence of pregnancy the test was always negative. Positive tests have been obtained as early as 8 days after the first missed menstrual period. The test remains positive for a few days following labor. In cases of death of the fetus, whether uterine or ectopic, the hormone continues to be present in the urine till the placenta is expelled or destroyed. In cases of hydatid mole, the test is positive and remains so as long as the mole is active.

The authors conclude that, in the hands of experienced workers who are familiar with the reactions in male mice, the test is sufficiently definite to be of great practical value.

A. L. McDONALD.

THE INFLUENCE OF A SALT-FREE DIET UPON LABOR: Hofstein and Petrequin (Strasbourg) (Gynecologie et Obstetrique, Tome XXIV, No. 2). The authors noted that certain women, who had been placed upon a salt-free diet for therapeutic reasons, were able to deliver themselves rapidly and comparatively painlessly. In the case of two primiparas the total period of labor was three and one-half and four and one-half hours, and for two multiparas the time was two and one-half and three and one-half hours.

A study of the literature failed to furnish any explanation. Studies of the chloride content of the blood in some twenty women during labor, in order to determine any possible relationship between the chloride content and duration of labor, gave inconclusive results.

A group of seven women were placed upon a rigid salt-free diet for from two to six weeks preceding labor. In the case of five primiparas, the period of dilatation was from two and one-half to five hours; with two multiparas, the period was one and six hours. The authors offer no explanation but consider the findings suggestive.

A. L. McDONALD.

THE USE OF AN ANTERIOR PITUITARY LUTEINIZING SUBSTANCE IN THE TREATMENT OF FUNCTIONAL UTERINE BLEEDING. Emil Novak and G. B. Hurd (Am. Jour. Ob. and Gyn., Vol. XXII, No. 4). Functional uterine hemorrhage in young women frequently recurs following curettage. Radiation therapy is too uncertain in these individuals. Repeated curettage may tide over till an equilibrium is reached. The pathological findings in ovary and endometrium are somewhat characteristic.

The ovary shows persistence of an unruptured graafian follicle and absence of corpus luteum. The ovarian disturbance consists of a persistence and excess of follicle stimulus, with an absence of the progestin influence, corpus luteum. This is confirmed by findings in the endometrium where there is no evidence of changes usually produced by the progestin furnished by corpus luteum. The prolonged influence of the follicle hormone without the inhibitory effect of progestin causes menorrhagia. The condition in the endometrium is not a true hyperplasia, but represents a persistence and exaggeration of the interval stage. The authors consider that these disturbances are due to abnormalities in the pituitary anterior lobe secretion.

Investigators agree that the anterior lobe produces two hormones: "Prolan. A" concerned with follicle growth and ripening; "Prolan. B" concerned with luteinization in the ovarian follicle. The pituitary secretion is increased during pregnancy and large amounts are found in the urine. Zondek has isolated both hormones in watery extract from the urine. The dominating influence of the secretion as isolated from the urine during pregnancy is to stimulate luteinization, increase the size of the uterus and ovary. The characteristic finding in these cases of bleeding is absence or deficiency of luteinization. Theoretically, the administration of corpus luteum extract should re-establish a balance. This has not been possible in practice.

A substance containing Prolan. B should convert the granulosa cells of the ovary to lutein cells and supply sufficient progestin to maintain a proper balance. The authors have been working with a substance obtained from the urine of pregnant women, a concentrate precipitate, with inert matter removed. While varying in strength they found that in experimental animals the extract produced luteinization. Theoretically, if this could be accomplished in the patient, the ovaries would produce their own progestin, and effect an equilibrium. The material used has been freed of the follicle hormone, Prolan. A, is non-irritating and non-toxic.

The dosage was arbitrarily established at 200 rat-units by intramuscular injection, daily. They hope to secure luteinization of the granulosa cells of the ovary, and thereby transform the "Stationary Hyperplastic" condition of the endometrium to the pre-gravid form, thus re-establishing a balance. The results were often too rapid for this explanation and seemed to be due to direct effect upon the unknown bleeding factor.

In all but seven of fifty-one cases the results were prompt and striking.

A. L. McDONALD, M.D.

MEDICINE

TUBERCULOSIS ABSTRACTS*

Sanocrysin (sodium-gold-thiosulphate) was announced by Mollgaard in 1924. Clinical observations of the effect of the drug, published by numerous European writers since then, have been decidedly variable. Generally speaking, favorable results have been reported of cases with the exudative type of lesion, while little clinical improvement has been noticed in cases of the chronic type. Since some of the clinical reports do not seem to justify the conclusions drawn, a group of investigators in the William H. Maybury Sanatorium in Michigan decided to make an intensive study of the effect of sanocrysin on a small, carefully selected, closely comparable group according

---

*From *Tuberculosis Abstracts*, a review for physicians issued monthly by the National Tuberculosis Association, Vol. V, Number 1, January, 1932.

to a prearranged plan. Results of the study were published in the October, 1931, American Review of Tuberculosis, of which the following is a brief abstract.

A TRIAL OF SANOCRYSIN

Mollgaard claimed that sanocrysin has a specifically curative effect on tuberculosis. He believed that the drug, introduced into the blood stream, permeates tuberculous lesions and there kills many, if not all, of the tubercle bacilli. Exudative, not too acute, pulmonary lesions of early age, being more pervious than the fibrous type, were considered more responsive to treatment. The fever, albuminuria, eruptions, and loss of weight resulting from the treatment were attributed to the liberation of toxins from the disintegrated bacilli. To offset the ill effects, an anti-serum was developed, and this was administered at the first sign of reaction; namely, albuminuria.

Other workers used the drug, as well as various other gold compounds, in human cases. The amount of gold in these compounds varies greatly; sanocrysin contains 37.4 per cent of gold. The present consensus of opinion seems to be that the chemical is not a specific bactericide, that nevertheless favorable responses sometimes occur, and that the toxic properties of the drug compel consideration. Metallic poisoning, rather than tuberculin-like shock, seems to account for the unfavorable reactions; consequently, Mollgaard's anti-serum has been discarded by most clinicians and smaller doses of sanocrysin are given.

PLAN OF TRIAL

The treatment was explained to a group of patients of the William H. Maybury Sanatorium. The 24 patients who were finally chosen from among the volunteers were all in good general condition, who would, therefore, not be likely to suffer ill effects from the drug. Most of them had benefited to some extent by the routine sanatorium treatment, but the healing of their disease was slow and incomplete. The lesions were chiefly of the exudative and mixed exudative-productive types. All were free from complications.

On the basis of clinical, X-ray and laboratory findings, the patients were then divided into two equal and comparable groups, cases being matched one with another as closely as possible. By a flip of the coin, Group I was designated as the sanocrysin-treated and Group II as controls. The patients themselves were not aware of any distinction in treatment.

METHOD OF OBSERVATIONS

The patients were put to bed for a month prior to starting any medication, during which time uniform data and information were collected to serve as a basis of comparison. The preliminary thirty days' study was carried out in the following manner:

1. The chest was examined biweekly, particularly to determine any variation in the extent or distribution of the râles, the findings being described in the record.
2. The chest was X-rayed (stereoscopic) at the beginning and at the end of the month and the films preserved, special notes of any changes being recorded.
3. Careful records of the presence and clinical course of complications and symptoms were made.
4. The sputum was weighed daily, and this figure was charted; also averaged at the end of the month.
5. The sputum was examined microscopically every two weeks to determine the presence of tubercle bacilli. A method of sputum concentration and animal inoculation was used routinely when indicated.
6. Body weight was measured and recorded weekly.

At the end of this preliminary checking, the same routine was continued during the period of the trial, except that physical examinations were done more frequently, particularly to show the presence and behavior of perifocal reactions, and stereograms of the chest were made monthly; oftener in cases showing rapid change.

Each patient receiving sanocrysin (Group I) was started with 0.1 mg. of the drug, dissolved in 2 c.c. of distilled water and injected into a cubital vein. At intervals of four days, unless contraindicated, additional injections were given, increasing by 0.1 gm. up to 0.3 gm., and then increasing to 0.5 gm. The amount of distilled water was increased to 5 c.c. when the dose of sanocrysin exceeded 0.3 gm. The 0.5-gm. dose was then repeated until the course was completed. The number of injections varied from nine to fourteen, and whenever there was a suspicion of a dangerous reaction the next dose was reduced, omitted or postponed. The total amount of sanocrysin administered to single patients varied from 3.1 to 6.1 gm., while the total amount per kgm. of body weight varied from 0.6 to 0.1 gm. The patients treated as controls (Group II) each received 14 intravenous injections of distilled water (2 c.c. each) at intervals of four days.

EFFECTS OF TREATMENT

The detailed effects on the tuberculous conditions are minutely described in the article. The observations include the effect on temperature, pulse, lassitude, body weight, cough, sputum, appetite, sleep, physical findings, pain in chest, hemoptysis, dyspnea. Similarly, the toxic effects referable to the drug are noted as these affected the skin, nerves (neuritis), mucous membrane, eye, gastrointestinal tract, liver, kidney, etc. Laboratory evidences were as carefully and as fully studied. The study lasted approximately six months, during the first two of which sanocrysin treatment was given. During the entire period of the trial, both groups were kept in bed.

A follow-up of patients was instituted one year after the close of the study. In finally determining the effects of the treatment, all the observations were correlated. Chief reliance was placed on such factors as changes in the X-ray shadows of pulmonary lesions, presence or absence of tubercle bacilli in the sputum, measurable symptoms such as temperature, and fluctuations in body weight. Changes in physical signs were not given much value. Toxic effects of the drug were distinguished as far as possible from symptoms referable to the disease itself. A summary of the results is as follows:

	Group I (Sanocrysin)	Group II (Control)
Number	12	12
Slightly improved	5	6
Much improved	1	1
Unchanged	0	3
Slightly worse	1	1
Much worse	4	
Slight toxic effect	8	
Severe toxic effect	3	
Fatal	1	

CONCLUSIONS

"1. This investigation proves the need and the merit of a carefully prearranged plan to be followed in a clinical test of a chemotherapeutic agent in tuberculous patients.

"2. We discovered no evidence in 12 cases, studied according to such a plan, that sanocrysin, given in small, gradually increasing doses up to a total of 6.1 gm., has a beneficial effect on pulmonary tuberculosis or its complications.

"3. Compared with 'control' cases, more of our sanocrysin-treated cases became worse. The evidence is strongly suggestive that sanocrysin was at least partly responsible for the unfavorable trend of the disease in some of these cases.

"4. Sanocrysin exerted definitely harmful systemic effects in all our treated cases, partly as a secondary result of its action on the local tuberculous lesions, but mostly, we believe, by virtue of its own inherent toxicity. These effects were usually on the nutrition, gastrointestinal function, temperature, skin, mucous membranes and kidneys.

"5. One sanocrysin-treated patient died from parenchymatous degeneration of the liver and other effects which we interpret as gold poisoning. We could not anticipate this unfortunate outcome.

"6. Because of the lack of definite evidence of benefit and because of positive evidence of harm which in some respects is long-lasting, especially in the kidneys, the use of sanocrysin, as we used it, is not justified."—*Sanocrysin in Pulm. Tuberc., J. Burns Amberson, Jr., B. T. McMahon, and Max Pinner, Am. Rev. of Tuberc., Oct., 1931.*

PEDIATRICS

TREATMENT OF ANEMIA OF INFANCY WITH IRON AND COPPER: H. Joseph (Bull. Johns Hop. Hosp., XLIX, 246, No. 4, October, 1931). In this paper Josephs reports a study of the treatment of so-called "secondary anemia" of infancy with iron and copper. The investigation was conducted on a group of infants ranging between three months and two years of age. The iron was administered in the form of a 10 per cent solution of ferric ammonium citrate, giving 2 c.c. per kilogram of body weight per day. The copper was administered in the form of a 0.5 per cent solution of copper sulphate, giving 1 c.c. per kilogram of body weight daily. From these studies Josephs found that copper accelerated the rise in hemoglobin when given in addition to iron. This acceleration was most evident when the hemoglobin was above 50 per cent, for above this point the hemoglobin curves from cases on iron alone tended somewhat to flatten out, whereas those from cases on iron and copper continued to rise steeply up to about 70 per cent. In this series it made no difference in the speed of recovery whether the child was on a diet of milk alone, or whether vegetables or eggs were included, and medicinal iron was found to be superior to food iron in causing a rapid recovery. The effect of the iron is first on the reticulocytes, then on the hemoglobin, and there usually exists a latent period before the effect on the hemoglobin is manifested by a rise. The end of the latent period appears to coincide with a sufficient rise in reticulocytes. Copper appears to accelerate hemoglobin formation, and has no effect on the reticulocytes.

C. A. STEWART.

DIE KLINISCHE BEDEUTUNG DER CRANIOTABES: I. Jundell (Acta Pædiatr., XII:1:1-40, September, 1931). In order to determine whether or not craniotabes was of clinical significance in the diagnosis of rickets, the author tested out the value of antirachitic treatment in a group of 129 infants. In all cases, the mothers were given either cod liver oil or vigantol before delivery, and the infants were similarly treated after birth. A control group of seventy-nine infants was kept on the same regimen of feeding and supervision, but given no anti-rachitic treatment. Monthly observations were made in most cases. In a few infants of each group a supra-occipital craniotabes was detected during the first month; the incidence gradually increased until the fifth month, when 65 per cent of the treated group and 58 per cent of the controls showed this type of craniotabes. After the fifth month, there was continuous evidence of healing until the 13th month, when no craniotabes was found in either group. A softening of the parietal bones occurred in 31 per cent of the treated cases and in 25 per cent of those untreated; this softening was noted in the largest number of cases in both groups during the third month and disappeared in both after the sixth month. There was no effect of antirachitic treatment apparent in either of these types of craniotabes.

During the 15 months period over which these infants were observed, clinical signs of rickets (*i.e.*, rosary or enlarged epiphyses) were definitely noted in two of the treated cases and 18 of the controls. On every visit after the fourth month, X-ray plates were made of the right hand, whenever possible. One infant out of 110 of the treated group showed evidence of mild rickets, which had entirely healed one month later; ten of the fifty-nine control infants were found to have signs of mild or severe rickets. The author therefore concludes that specific treatment which prevents rickets has no effect on craniotabes, and that the latter should not be looked upon as a clinical manifestation of the disease. He believes rather that craniotabes is a physiological or simple hypoplastic phenomenon and suggests that it might be produced by the pressure of the growing brain against the bones of the head while the child is in a horizontal position—a condition which would not obtain in primitive tribes where the infant is carried in a vertical position for the greater part of the day.

VACCINE TREATMENT OF ASTHMA IN CHILDHOOD: A. Graeme Mitchell, M.D., and Merlin L. Cooper, M.D., Cincinnati (Arch. Ped., December, 1931, Vol. XLVIII, No. 12). Practically it appears that the asthmatic patient is hypersensitive, or, to employ more acceptable terminology, allergic, to certain substances which in most instances are obviously protein in nature. Whether the allergic state is inherited or whether it is acquired, removal of contact or desensitization of the patient may be curative so far as the attacks are concerned. It is this fact which is taken advantage of in treatment.

A certain number of cases of asthma are associated with upper respiratory tract infection. That is to say, the paroxysmal attacks follow acute nasopharyngitis.

In the authors' work with asthma as it relates to upper respiratory tract infections, they carefully cultured the material obtained by swabs from the patient's nose and throat, preferably during an attack of acute upper respiratory tract infection, testing the skin sensitivity to the various microörganisms obtained; preparing and injecting mixed vaccine made from the individual vaccines of the microörganisms to which the patient was skin-sensitive by intracutaneous test. In treatment, one-half to one minim was injected subcutaneously, and, depending upon the degree of local reaction, which should not be too severe or last more than twenty-four hours, this dose was repeated or increased daily until a maximum of eight minims was reached, upon which this amount was given two or three times a week for several weeks longer.

Some authors have obtained equally good results in asthma with stock as well as with autogenous vaccines, and it has been reported that injections of tuberculin cause the arrest of asthmatic attacks.

A certain number of children, whose asthmatic attacks are associated with upper respiratory tract infections, are decidedly benefited by vaccines and in some instances attacks, which have previously been frequent and severe, cease for months or years after such treatment. Vaccines may be helpful when other methods have failed.

It is not clear whether the vaccine treatment acts by specific desensitization to microörganisms which the patient harbors in his nose and throat and which may be causative of the asthmatic attacks, or whether the mechanism is simply one of non-specific protein therapy.

Every child suffering from asthma, especially when the attacks are associated with upper respiratory tract infection, should be given the benefit of a trial with treatment by a properly prepared and administered vaccine when other measures of treatment fail.

R. N. Andrews, M.D.

IMPETIGO CONTAGIOSA NEONATORUM: Irwin Rubell, M.D., Chicago (Arch. Ped., Dec., 1931, Vol. XLVIII, No. 12). The lesions observed in our series grouped themselves into three types: The bullous, the pustular and a third group for which the term sebaceous would seem appropriate. All three types of lesions frequently occurred simultaneously in the same patient.

Labhardt and Wallart, in their cases of congenital impetigo, obtained the staphylococcus, and occasionally the streptococcus or diplococcus.

The course in most cases was benign and the outcome favorable. However, complications may occur and be very severe or even fatal. One patient, suffering from an extensive pemphigoid eruption with much exfoliation, developed bronchopneumonia to which he succumbed.

Prophylaxis: All babies received a daily sponge with 1:5000 bichloride of mercury which was rinsed off with clear water within two minutes. The scales were washed daily with a 1:1000 bichloride. In order to avoid excessive handling and possible contamination of babies' clothes, the following technic was carried out: Upon delivery from the laundry, the various articles of infants' wear were sorted into separate bundles, labelled and sent through the operating room sterilizers. The nurses would then use sterile forceps to remove the articles needed. No one was permitted into the nursery except the nurses actually on duty there. Attending physicians had to wear gowns and gloves when examining infants.

A baby once removed from the well nursery was never returned there. A mother suffering from an infection of any kind was transferred to another floor, and the baby removed to the children's ward. Visitors to the mothers were limited to two a day and were excluded from the room when the baby was brought in for nursing. Overcrowding of the nursery was an important factor in spreading the infection.

Treatment: In response to a questionnaire, the Society of the Lying-In-Hospital of New York states that exposures to the alpine sun-lamp gave the most satisfactory results. In the author's cases, the lesions were opened as soon as discovered, touched up with 95 per cent alcohol, followed by the application of two per cent ammoniated mercury ointment.

ROENTGENOLOGY

INDICATIONS FOR VARIOUS RADIOLOGICAL PROCEDURES IN THE EXAMINATION OF THE LUNGS: RADIOSCOPY, TELERADIOGRAPHY, STEREORADIOGRAPHY. Dioclès and Azoulay (Revue de la tuberculose, 1931, XII, 957).

According to these members of the staff of the Hotel Dieu in Paris, Radioscopy is a useful procedure and may even be substituted for radiography in certain cases, as in the examination of patients with advanced lesions in dispensaries, where on account of the expense and labor involved it would be impracticable to make a film in every case. It has the advantage of permitting changes in the position of the patient and of showing the movements of the heart, lungs and diaphragm. They recommend that skiascopy be always used before a film is taken in order that the best position for taking it may be determined. Radioscopy alone should not be relied upon if negative when the history of the case suggests the presence of lesions too fine to be detected by it.

Teleradiography must *always* be used in taking chest films according to these writers. Their technic is as follows: A fine focus tube is used (3 millimeter or less), *a distance of 1.5 to 2 metres,* an exposure of a tenth of a second or less, a high kilovoltage (120 to 150 kilovolts) and an amperage of 100 to 150 milliamperes. In certain cases as in pleuro-pulmonary sclerosis or very extensive infiltration, the "rotating antidiffuser" (Stephani), which seems to be a kind of very rapidly moving Bucky diaphragm, may be used in addition, but this is rarely necessary.

Stereoradiography permits better localization of lesions and determination of relations than the use of flat films. The writers recommend it when oblique films are taken as well as when antero-posterior or postero-anterior films are used. The posterior left oblique position gives good pictures of the posterior mediastinum, the bifurcation of the trachea and of the mediastinal gland area. The posterior border of the left heart is thus clearly defined. This is the position of choice in the study of adenopathy and of tumors of the mediastinum. The anterior right oblique position gives excellent views of the mediastinum, of the aorta, and of its crossing over the trachea and of its bifurcation. Lipiodol injections with stereo-radiography may help to determine the significance of puzzling shadows, for instance one at the right base, above the diaphragm, which may be due to bronchiectasis, to pleural thickening, to an abscess of the lung, to interlobar, mediastinal, or diaphragmatic pleurisy, to pyothorax, to abscess of the liver, cancer or suppurating hydatid cyst.

SURGERY

PLANTAR TENDERNESS AS AN EARLY SYMPTOM OF THROMBO-PHLEBITIS. Dr. Gerhardt Tschmarke, Leipzig (Der Chirurg, Volume No. 3, Number 21, November 1, 1931, Page 924). Payr is the first to call attention to a tenderness, experienced by the patient on pressure of the sole of the foot, as an early sign of thrombo-phlebitis in the veins of the lower extremities. Observation at his Clinic since then has corroborated this sign as worthy of observation. For example, in sixteen cases of primary thrombophlebitis in the veins of the foot and calf, five times this plantar sensitiveness was the only symptom to call attention to the condition, whereas eleven times it was associated with other subjective and objective signs. Cases of thrombo-phlebitis, which otherwise would escape attention, can in this way be discovered, and proper measures taken to prevent complications, such as embolus.

The statistics show that over a period of years, in thrombo-phlebitis was recorded as occurring in 1 to 2 per cent of the cases, but with this sign as an index, further observation showed evidence of thrombo-phlebitis in as many as 16 per cent of the cases. These latter cases were not recorded as thrombo-phlebitis unless, aside from the objective plantar tenderness, there were also, later, other objective signs, such as edema and measurable swelling. It was the author's experience that either immediately or within the next twenty-four hours after the development of this tenderness, other signs would show, such as edema and swelling, infiltration of the calf of the leg, and muscular resistance against passive dorsal flexion of the foot.

In the absence of any objective signs of thrombophlebitis, one is apt to overlook or minimize the patient's complaint of paresthesia in the foot, or a sense of tension in the calf of the leg. If, however, the tenderness in the sole of the foot is present, one can look for further trouble in the development of thrombo-phlebitis within the next twenty-four hours. For that reason the author considers this finding the earliest sign of thrombo-phlebitis.

It has been the experience of the author that the earlier treatment is established the better one can avoid complications. Likewise, early treatment will cause a much quicker resolution of the thrombo-phlebitis than if the condition is allowed to advance. As soon as this sign is elicited, the author elevates the extremities in a comfortable position on pillows, uses dry hot air several times daily to cause an erythema of the skin—in the interval using hot compresses of 30 per cent alcohol or subacetate of aluminum solution.

Thus, the author concludes, the detection of tenderness on plantar pressure is an early sign of thrombophlebitis, which can be elicited by routine examination daily. The value of this sign is in the prevention of complications by early treatment.

A. E. SOHMER, M.D.

THEELIN AND AMNIOTIN

The new preparations of ovarian hormone, such as Theelin and Amniotin, have been used in a large number of cases of troublesome menopausal symptoms, but the results obtained are by no means uniform. In many cases, no relief at all is obtained, whereas in others the benefit derived is excellent. In some cases in which good results are observed, part of the success may be attributed to the psychologic effect of the injections. (Jour. A. M. A., December 12, 1931, p. 1822.)

OBITUARY

(Continued from page 192)

own specialty but also in the wider fields of medicine. He was not a great contributor to medical literature but was a keen observer, an excellent teacher. Ever tolerant of the opinions of others, his criticism was ever tempered with kindliness and praise for the younger man and his work. With continued interest in educational matters during later years, his greatest joy was the education, progress, and success of his worthy son, recently made professor of physiology at Yale.

No greater tribute to the generous and humanitarian side of John Fulton can be written than the noble and unselfish service he rendered to the poor, by faithful daily attendance upon his clinic at the Wilder Dispensary of St. Paul during the last fifteen years of his life. In fact, his renewed interest and devotion to his profession, and his active participation in all medical societies during these years was an inspiring example for his young colleagues. Nature gifted him with a remarkable constitution and a strong will to overcome sometimes overwhelming obstacles. The younger generation could hardly think of John Fulton as one of the pioneers of medicine because of his alert mind, sustained enthusiasm, and energy right up to the time of his death.

Your committee is privileged to express its deep appreciation of John Farguahar Fulton, whose kindly nature we loved and admired, whose departure fills us with fond memory of valued friendship. We, the benefactors of his early work, admirers of his noble example and his sterling qualities, extend for the medical profession our sympathy to Mrs. Fulton and his son and daughters in their bereavement.

Orville Whipple Parrott

1863-1932

Mr. O. W. Parrott, Minneapolis, for fifty years active in the publishing business in the Twin Cities, passed away after a brief illness on February 13. Associated with the Bruce Publishing Company and its predecessors in the ownership of the publications of the Commercial Bulletin Company for the past forty-five years, Mr. Parrott had been production supervisor of some thirty-six monthly publications produced in the plant of the Bruce Publishing Company, one of which has been Minnesota Medicine.

It was the privilege of those associated with the publishing of the journal to know Mr. Parrott, and knowing him, even though it was only by occasional contact in connection with the publishing of the journal, was to appreciate the kindly qualities of a gentleman, always accommodating and an expert in his field.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

Surgical Errors and Safeguards. Max Thorek, M.D. Surgeon-in-Chief, The American Hospital, Chicago, Attending Surgeon, Cook County Hospital, etc. 696 pages. Illus. Price, $10.00. Philadelphia: J. B. Lippincott, 1932.

Surgical Pathology of the Female Generative Organs. Arthur E. Hertzler, M.D. Surgeon to the Agnes Hertzler Memorial Hospital, Halstead, Kansas, etc. 346 pages. Illus. Price, $5.00. Philadelphia: J. B. Lippincott, 1932.

The Story of Medicine. Victor Robinson, M.D. Professor of History of Medicine, Temple University School of Medicine, Philadelphia. 527 pages. Price, $5.00. New York: Albert and Charles Boni, 1931.

Cancer: What Everyone Should Know About It. James A. Tobey, Dr.P.H., Fellow American Public Health Association, etc. 320 pages. Illus. Price, $3.00. New York: Alfred A. Knopf, 1932.

Psychology and Psychiatry in Pediatrics; the Problem. A Publication of the White House Conference. 146 pages. Price, $1.50. New York: The Century Company, 1932.

Body Mechanics: Education and Practice. A Publication of the White House Conference. 166 pages. Illus. Price, $1.50. New York: The Century Company, 1932.

The Principal Nervous Pathways. Andrew Theodore Rasmussen, Ph.D. Professor of Neurology, Dept. of Anatomy, University of Minnesota Medical School, Minneapolis. 73 pages. Illus. New York: The MacMillan Company, 1932.

Sydney University Reprints. Series IX. Medical Sciences (Non-Clinical). Illus. Sydney, Australia: The Australasian Medical Publishing Company, Ltd. 1928-1930.

Koryza. Hermann Ernst. 104 pages. Illus. Vienna, Austria: Druck der Vernay A.-G., 1931.

PHYSICIANS' MANUAL OF BIRTH CONTROL: Antoinette F. Konikow. 245 pages. New York. Buchholz Publishing Co., 1931.

This is a volume of some 230 pages and there is no doubt that the author is very familiar with the use of birth control measures. She enumerates all the various methods in use and gives her opinion of their reliability, convenience and cost. She also gives her method of carrying out birth control measures; her reasons for doing so, and her reasons for not doing so in certain cases.

The third part of her book is devoted to various tables setting forth the various economic factors that have a bearing on this subject and tables showing the various methods used and success obtained as well as the patients' comments. The author reviews the methods and statistics from foreign countries and gives her record of some 500 cases of her own. The book is a complete presentation of the subject.

A. G. Schulze, M.D.

A DOCTOR OF THE 1870'S AND 80'S. Wm. Allen Pusey, A.M., M.D., LL.D. 153 pages. Illus. Price $3.00. Springfield, Ill.: Chas. C. Thomas, Publisher, 1931.

A delightfully written tribute written by a doctor son to his father, also a doctor, who belonged to the preceding generation and who represented the fine type of general practitioner.

The younger practitioner of today could read this volume with interest and would appreciate the hardships of practice fifty years ago when horses and saddle bags were in vogue and bacteriology was unknown, but when the returns for practice were doubtless fully as satisfying as in our day.

C. B. Drake, M.D.

DIABETES DIRECTIONS FOR TREATMENT BY INSULIN AND DIET. Benjamin F. Smith, M.D., D. Appleton & Company, New York. 1930. Price, $2.00.

Another volume for the diabetic patient. The brevity of its instructions recommends it. The great number of daily menus given facilitates the instructions given the patient. The method of substitution of combinations of food for those given in the diets in the reviewer's opinion complicates matters unnecessarily. There is no need for this or additional diabetic manuals.

C. B. Drake, M.D.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

FOR SALE—Office equipment including X-ray. Location in Minnesota town of 1,400 people. Average income of over $5,000 yearly for the past eight years. Unopposed. Specializing. Address D-150, care Minnesota Medicine.

WANTED—Affiliation with busy surgeon or practitioner in Minnesota. Ten years' surgery and general practice. Address D-165, care Minnesota Medicine.

THREE GENERATIONS of experience in grinding, specializing in fine surgical instruments. Prices, reasonable. Schwarz Grinding Service, Foot-Schulze Bldg., 128 10th St. E., St. Paul. Telephone, Midway 9939.

WANTED—FIRST CLASS EYE, EAR, NOSE and THROAT man to become associated in a Minneapolis Clinic. Complete equipment. State postgraduate work, and experience. Address D-164, care Minnesota Medicine.

FOR SALE—$10,000 cash, general medical and surgical practice, Minnesota. Some cash required. Address D-163, care Minnesota Medicine.

CATHOLIC PHYSICIAN WANTED—Established practice. Good roads. Garden spot of Minnesota. Little to buy. Reason retiring. Address D-166, care Minnesota Medicine.

FOLLOWING UP SANATORIUM PATIENTS*

George Thomas Palmer, M.D.
Springfield, Illinois

REGARDLESS of the brilliant progress in tuberculosis work as shown by the decrease in tuberculosis mortality, one who has followed the anti-tuberculosis campaign closely for a quarter of a century is still rather depressed by three outstanding facts: (a) the continued delay in diagnosis until an advanced and incurable stage of the disease has been reached; (b) delay in seeking sanatorium care until the chances of recovery or material improvement are slight; (c) the excessive rate of reactivation among patients who have been discharged or who have left sanatoria in apparently good condition.

The evidence that we have by no means reached the place we should strive to attain in educational and clinical service leading to early diagnosis, is apparent to every physician and nurse engaged in tuberculosis work and especially to those connected with sanatoria. Despite our educational efforts, the public, and even those who are in daily contact with open cases of tuberculosis, are not yet convinced of the importance of periodic re-examination. So far, we have failed to sufficiently interest the medical profession to the point where we have any assurance that an examination will lead to a diagnosis of active or well advanced disease.

Neither the doctor nor the layman has been impressed with the value and economy, both in human life and money, of early sanatorium care, nor with the usual futility of home care.

At any rate, in this day of self-congratulation and advancement, we still witness the doleful procession of advanced consumptives entering our sanatoria. It is still not unusual to have death occur within a few weeks after sanatorium care is sought or even in the interim between application for admission and the finding of a vacancy. In our own institution, it is still necessary to maintain 60 per cent of our beds as infirmary or hospital beds and 40 per cent as ambulant or semi-ambulant beds.

This gloomy spectacle of failure to secure diagnosis and sanatorium care until death is near at hand, may not be so frequent or conspicuous in certain fortunate and favored localities in the Mississippi Valley where great public interest has been aroused and where unusual public machinery has been created; but, in my own State, at least, these exceptionally favored spots are very few and far between. However, that is not the question that I propose to discuss today.

Someone has said that of curable consumptives, seventy-five per cent lose their chance of recovery after the symptoms of the disease have practically disappeared. The outstanding discouragement of my own twenty years of sanatorium management, is not failure to attain improvement or arrest while the patient is in the institution, but the unnecessarily high percentage of reactivation—the excessive morbidity and mortality—within a few years after leaving the sanatorium.

What I have to say of our efforts to overcome or to prevent this reactivation will not be especially interesting to those who are located in communities where there are ideally operated municipal or county sanatoria with entirely adequate dispensary and visiting nurse service (if there are such comunimties); but our problem is not unlike that of the state sanatoria or others serving a wide area of territory, without competent visiting nurses or other field staff.

The excessive percentage of reactivation and high mortality rate among those who are discharged from sanatoria in good condition may be due to faulty sanatorium education and training, but is more likely due to improper guidance on reaching home, to failure to obtain the cooperation and moral support of the family, and to the restlessness and sense of irresponsibility on the part of the patient. It consequently appears that the most effective course which the sanatorium can follow to assure permanency of its results, is that which will give the greatest influence over the patient while in the institution and that which gives the patient the greatest degree of support and supervision following his discharge.

---

*Presented before the Mississippi Valley Conference on Tuberculosis, St. Paul, Minnesota, September 21, 22, and 23, 1931.

In our own sanatorium the foundation for the follow-up or home control of the patient is begun the day he enters the sanatorium. Inasmuch as the later home contact is a job which I have assigned to myself, and which must be the work of one man, I invariably take the patient's initial history, having my Superintendent write the record from my dictation so that she, who will guide the details of his sanatorium life, and I, who will follow him through his illness, may be fully familiar not only with his physical condition, but his temperament, his personality, and his personal and domestic problems. It is almost as important to know what kind of a family the patient has to live with as to know the extent of his pulmonary involvement. An unlimited time is allowed for the initial story and the patient is encouraged to talk freely. A special effort is made to bring out all of those factors in his life which may have contributed to his reduced resistance and the activation of the disease so that these factors may be recognized and guarded against when the patient resumes his home life. The patient is then advised that at any time during his sanatorium stay he is welcome to unlimited interviews as to his physical condition or personal affairs and in these interviews an effort is made to learn still more of the environment and problems which will confront the patient on his discharge. It may require several such interviews before the patient's confidence is won and his reticence entirely overcome.

When the patient is ready for discharge there is a final interview in which all details which will confront him are brought together and made a matter of record and the patient is given a written outline for his home guidance, this outline being prepared for the individual patient with his personal problems thoroughly in view and never in stereotype form.

At this point the further relationship of the sanatorium with the patient is determined by the attitude of the family physician and this is influenced very largely by the close contact maintained with the doctor during the patient's sanatorium care. If it is the desire of the physician that contact with the sanatorium should be terminated and the details of home care left to the patient, the sanatorium follows up the patient only in a purely impersonal way. As a rule, however, the family physician has come to prefer that the sanatorium shall retain as intimate contact with his patient as possible. Under these circumstances, the patient is supplied with temperature and record blanks which are to be filled out and returned to the sanatorium every two weeks and are to be accompanied by a brief note with information as to any unusual symptoms, as to the amount of exercise and any unusual events in the patient's life. He is assured that these will be regarded as confidential. These reports and letters are always answered by a letter more or less in detail, dictated by the Medical Director himself, and copies of these replies are sent to the patient's physician.

In many cases these semi-monthly letters have been exchanged between the patient and the sanatorium for periods of from two to five years and I believe that they have been particularly beneficial at that stage where the patient is ready to resume gainful occupation.

The patient is urged to remain for many months at least under the weekly observation of his physician and to advise us in his semi-monthly letters as to the opinions which the home doctors may express. Incidentally, it is remarkable how much difficulty the patients encounter in securing this prolonged supervision from their home doctors, especially when there is no evidence of acute illness. In such instances, a tactful letter to the doctor frequently alters his attitude.

If the family doctor prefers, as is frequently the case, the patient returns to the sanatorium for periodic reexamination and advice or is referred by the sanatorium to men specializing in tuberculosis in their own neighborhoods. In the latter case, the examining physician is always supplied with a brief case record and information as to the program the patient is following so that he may not be disturbed by what appear to him to be conflicting opinions and radical changes in routine.

A record of the home progress of every patient is kept on file in the sanatorium office and this record is brought down to date on each direct or indirect contact with the patient.

As a means of continuing its influence over discharged patients, the sanatorium publishes a little newspaper called the Palm Leaf which, unlike most of the sanatorium papers, is edited by the Medical Director himself. While this publication contains news items relative to former patients and events at the sanatorium which will prove of interest to former patients, its chief value lies in its continued systematic reiteration of those things which are essential to the patient's recovery and which are most likely to be ignored or overlooked by the convalescent patient. Our files contain scores of letters from former patients assuring us that the regular visits of the Palm Leaf have caused them to adhere more strictly to the program leading toward recovery.

Once in a while the Palm Leaf announces what we call a spiritual homecoming and every patient is requested to write to the Medical Director as to his progress and present condition and each patient is also requested to give the names and present addresses of all former sanatorium patients of whom they have knowledge. In this way the records of former patients may be constantly revised and, whenever a patient is found with whom we have had no contact for several months, a personal letter is written asking for a statement of his present condition.

It is our belief that this correspondence extending over several years with semi-monthly individual letters from the head of the institution containing advice, encouragement and necessary warnings has a decided influence on the action of the patient and a distinct influence on his recovery. The information gained from the patient while in the sanatorium, as to his home conditions, his financial status and his domestic problems, makes this correspondence infinitely more personal, more valuable and more helpful.

While there is no pretense that this method of the follow-up of patients is ideal or even adequate, it is none the less true that, in the opinion of a large group of physicians, this contact is one of the most valuable services rendered by the sanatorium. Its success depends upon the intimacy of acquaintance formed in the sanatorium, definite knowledge as to the patient's personal problems and home conditions and the manifestation of genuine interest in the individual. While this laborious service is rendered entirely without cost, it none the less taxes our ingenuity to sufficiently interest the patient so as to cause him to maintain his contact with the sanatorium over the prolonged period which we regard as essential to the best results.

AN OUTLINE OF SOME OF THE ADVANTAGES AND DISADVANTAGES OF VARIOUS AGENTS USED IN ANESTHESIA*

John S. Lundy, M.D.
Rochester, Minnesota

In considering the advantages and disadvantages of the various agents used in anesthesia one considers primarily the mortality and secondarily the morbidity associated with the anesthetic agent, both during operation and after operation, regardless of whether the outcome, other than in association with the anesthetic, is fatal. In my brief outline of some of the fundamental principles that guide one, in certain cases, in eliminating from consideration certain anesthetic agents, I shall consider, separately, the mortality that occurs during operation and after operation.

The factors of danger and the factors of safety of the various agents are essentially related to their pharmacologic effects, as modified by the method of, and the skill in, their administration as well as by the physical condition of the patient and the requirements of the operation.

PRIMARY CONSIDERATIONS

Immediate untoward results.—The more commonly used of both the new and the old anesthetic and analgesic agents divide themselves into two groups from the standpoint of immediate untoward results: (1) those in which there is little if any margin of safety between failure of the respiration and failure of the heart, and (2) those in which there is a wide margin of safety between failure of the respiration and failure of the heart. In the first group I would place chloroform, ethyl chloride, nupercaine (a-butyl-oxy-cinchonic acid diethyl-ethylene diamide-hydrochloride) and probably cocaine; in the second group, ether, nitrous oxide, ethylene (excluding explosions), procaine, avertin (tribromethyl alcohol) the barbiturates, and morphine.

---

*From the Section on Anesthesia, The Mayo Clinic, Rochester, Minnesota. Read at the meeting of the Northern Minnesota Medical Association, Hibbing, September 14, 1931.

Delayed untoward results.—The ordinary delayed untoward reactions which occasionally are associated with the use of certain agents may not be easily classified and probably are best pointed out by first mentioning the agents and then the complications. For example, chloroform causes delayed central necrosis of the lobules of the liver; ether, pulmonary and renal complications, and, if patients have diabetes, probably complications involving the pancreas. With the use of nitrous oxide delayed untoward results are not observed unless they are initiated by increase in blood pressure at the time of operation. Not infrequently anoxemia is seen during anesthesia with nitrous oxide. With the use of ethylene, delayed untoward reactions should not occur, unless, because of the inflammability of the agent, a burn has been produced which may later cause death. Ethyl chloride usually does not cause delayed untoward results. Early in the use of avertin colitis developed from its improper application, and patients with pulmonary tuberculosis and cavitation were unfavorably affected. In one case a diabetic patient suffered considerable postoperative shock which in my opinion was due to the avertin.

Delayed untoward results associated with local anesthetics must in part be associated with the trauma of the needle which introduces the agent into the body. For example, headache following lumbar puncture must naturally be expected in cases in which anesthetics are given intraspinally; in some instances the spinal cord may be traumatized, although this must occur rarely. Characteristic pharmacologic effects of the common local anesthetics would lead one to believe that they are not lasting if ordinary doses are used. However, this depends, to some extent, on the concentration of the solution used, and probably, also, on the condition of the nerve cells that make direct contact with the anesthetic. Respiratory embarrassment is associated with large doses of morphine, or of a barbiturate, or both. Pulmonary complications are common following an overdose of a barbiturate with or without morphine. Blood pressure may be lowered and the circulation of the blood slowed, which would tend to the formation of thrombi and emboli. As a rule the danger incident to the use of these agents is more or less proportionate to the dose employed. Under the term "balanced anesthesia," I have previously called attention to the advantage of using a small dose of two or more of these agents.

SECONDARY CONSIDERATIONS

The less significant advantages and disadvantages incident to the use of the various anesthetic agents also hinge on certain essential principles. These have to do with the answer to one or both of two questions: Does an anesthetic or special method of administering an anesthetic make an operation easy or easier than others? Is the use of a certain agent contraindicated by the disease or diseases present? In some cases relaxation is essential to the successful outcome of the operation, and, if other conditions permit, it may be advantageous to use spinal anesthesia, some form of regional block anesthesia such as sacral or brachial plexus block, or ether by the open-drop method. If relaxation is not essential, the gases, with or without ether, or local infiltration may be used. Often the quiet breathing associated with intratracheal anesthesia may be as advantageous as relaxation.

The disease conditions presented by patients are numerous, and a few only can be mentioned here, although they are important in the choice of the anesthetic. In the presence of active pulmonary disease, such as tuberculosis or bronchiectasis, an inhalation anesthetic which tends to irritate pulmonary tissue, such as ether, should be avoided, and gas used instead. However, if relaxation is necessary in such cases, spinal anesthesia may be resorted to for operations below the diaphragm, and for operations above the diaphragm some method of regional block or infiltration anesthesia might be used. In either event, gas may be added if the local or spinal anesthesia is insufficient.

If the patient has diabetes it is often wise to avoid the potent general anesthetic agents which tend to depress the functions of certain organs, and also to avoid the use of agents which must be destroyed in the body or excreted from it by organs which, because of disease, do not carry any additional burden well. Drugs, such as the barbiturates, are destroyed within the body or eliminated from it other than by way of the lungs, and continue to act until they are destroyed or eliminated; and so, their use is unwise in certain cases in which the functions of organs are seriously impaired. Avertin, too, theoretically may be contraindicated in certain conditions in which organic function is seriously impaired, especially in cases of advanced hepatic and renal disease. The admixture of epinephrine and local anesthetic is not advisable in the presence of hypertension or exophthalmic goiter. It is obvious that inflammable agents are contraindicated if the cautery or other devices which might ignite the anesthetic agent are to be employed. There are certain conditions, such as intrathoracic tumor, which require opening the thorax, and in which pulmonary ventilation and anesthesia must be accomplished simultaneously. In such cases satisfactory results may be more easily obtained if an intratracheal tube is used; the anesthetic is thus administered with oxygen. For many operations, especially plastic operations about the head and neck, the intratracheal method of anesthetization makes the work of the surgeon and the anesthetist easier. Since carbon dioxide increases the coagulability of the blood, patients who tend to bleed and whose clotting time may be delayed may benefit by the addition of carbon dioxide to the anesthetic mixture. This, however, is one of the least of the functions of carbon dioxide; at present this gas is used extensively to control the depth of respiration, to control nausea during spinal anesthesia, to control hiccough following operation, and to hyperventilate the lungs following operation, regardless of whether respiratory embarrassment has come about from overdose of an anesthetic agent or from the extreme effects of morphine or a barbiturate, or both.

Agents and methods available at the present time make it possible to avoid a practice which will probably be unsatisfactory, that is, the use of any anesthetic agent or method as a routine.

THE POCKET FLAP

THE SAFEST METHOD FOR EXTRACTION OF SENILE CATARACT*

Charles Nelson Spratt, M.D.
Minneapolis

IN Les Miserables, Victor Hugo vividly describes the panic that seizes the traveler who, walking along the sea shore at low tide, discovers that he is lost in the quicksands. A similar feeling often overwhelms a patient when told that he has a cataract. The thought of oncoming blindness to many is as terrible as death itself. If the diagnosis is correct and the loss of vision is not due to glaucoma with a hazy lens (often called cataract by the public) a cataract operation offers the greatest hope for the recovery of vision, if the fundus is normal.

From the patient's point of view the restoration of vision, and not the technic or method to be used, is the important problem. What operation will prove the safest and offer the least chance of loss of the eye, the recovery of useful vision, the shortest convalescence, the least postoperative discomfort? It is said that Barraquer, when asked what operation he would choose had he a cataract himself, stated that he would have it done by the intracapsular method, provided he were the operator. If he were not, he would prefer the capsulotomy operation. If the same problem were presented to any other ophthalmologist, I think that he would select the operation which he considered the safest, the one followed by the least number of failures.

The removal of the lens in capsule, which, according to Wood,[1] was first performed by Samuel Sharp of London in 1753 and advocated by Smith, Pagenstecher and Barraquer, is an ideal procedure in that no cortex or capsule remains to cause irritation. Certain operators, such as Smith and Barraquer, acquire a technic that possibly makes the intracapsular operation as safe as the capsulotomy method.

---

*Presented before the Section on Ophthalmology of the American Medical Association. Permission for publication obtained from the American Medical Association.

Statistics of excellent operators show that the intracapsular operation is followed by a greater percentage of loss of vitreous than when the capsulotomy operation is done. Zentmayer[2] reports in Smith's 17 operations in Philadelphia a 38 per cent loss; Birdwood[3] gives a 35 per cent loss in 311 operations; Elschnig[4] reports a 2 per cent loss in 144; Dunphy's[5] series at the Massachusetts Eye and Ear Infirmary shows a loss of 18.8 per cent in 441 cases; he also gives Derby's loss as 2 per cent in 200; Husain,[6] 11 per cent in 737 cases; Parker,[7] 18.8 per cent in 100 cases. The statistics of the capsulotomy operation show a much smaller loss of vitreous. Birdwood, in 1,585 cases, had a 10 per cent loss; Ellett,[8] in 600 cases, a 7.6 per cent loss; Dunphy, at the Massachusetts Eye and Ear Infirmary, in 1,821 cases, a 7 per cent loss; Parker, in 1,421 cases, 10 per cent loss; Graefe, as quoted by Barkan,[9] in 669 cases, 2.8 per cent; Ring (collected), in 1,123 simple extractions, 3.9 per cent; Ring (collected), in combined extraction, 6.9 per cent.

I believe that the loss of vitreous is a complication that should and can be avoided, since poor vision and a soft eye with ultimate loss may result. Dunphy has followed fifty cases in which a loss of vitreous occurred and reports that good vision (from 20/20 to 20/30) was obtained in 40 per cent; fair (from 20/40 to 20/50), in 22 per cent; poor (from 20/70 to 20/100), in 18 per cent, and bad (20/200 or less), in 20 per cent. In a rather humorous style, Fradkine[10] speaks of loss of vitreous as not a dangerous accident. He is inclined to think that this leaves a cleaner vitreous, as the cortex and capsule are washed out. This view is not held by other operators.

The operation that has given me the greatest number of successes, the most rapid healing, the shortest convalescence, and which I believe to be the safest operation, is the suture pocket flap method. This is a modification of the Husain flap operation, which in turn is a modification of the Czermark. The method of Husain was called to the attention of the American profession by W. Holbrook Lowell.[11] This consists in making an opening in the conjunctiva about 1 cm. above the sclerocorneal margin. The conjunctiva is dissected to the limbus, and an opening is made with a keratome into the anterior chamber beneath this flap. This incision is enlarged on each side with scissors. The lens is extracted in capsule after an iridectomy. No suture is used unless vitreous is lost.

In May, 1928, I[12] published a description of an operation with a report of fifty-two cases. The method described in that article has since been followed without change.

PREPARATION

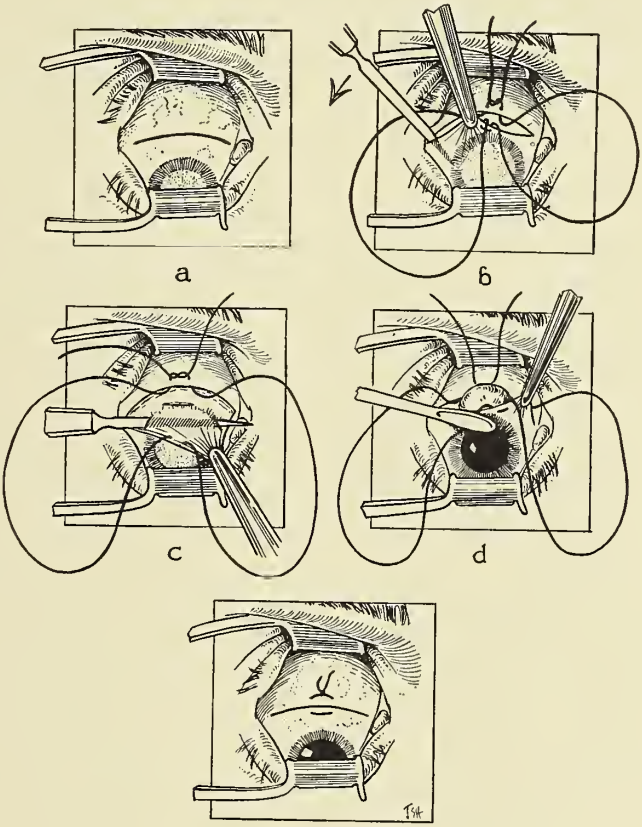
The patient is given 20 grains (1.3 Gm.) of barbital or 10 grains (0.65 Gm.) of phenobarbital four hours before the operation and the pupil is dilated with 1 per cent atropine. The operation is done on the patient's own bed or on a stretcher. The skin is washed with full strength hexylresorcinol solution S. T. 37. Anesthesia is produced by four instillations of 4 per cent cocaine at four minute intervals. Subconjunctival or Van Lint injection of the lids with procaine hydrochloride, or paralysis of the orbicularis muscle by the injection of the facial nerve as suggested by Dilliard,[13] have not been made, nor have I used deep orbital injections, as this method is not entirely free from danger. Brusselmans[14] reports a case of cellulitis following deep orbital injections, and McCannel[15] has had a fatal case of cavernous sinus thrombosis.

Many writers seem to think that the orbital injection of a local anesthetic is a recent idea. It may be of interest to quote the suggestion of Halstead in 1884, reported by his assistant Hall:[16] "In addition to the usual application to the conjunctiva, in operations on the eye, an injection into the orbit, in the neighborhood of the ciliary nerves, would doubtless diminish the liability to a very grave accident, . . . namely, in extrusion of the lens, from blepharospasm, occurring during iridectomy performed with the aid of cocaine." It may be noted that Halstead was also the first to use cocaine as an anesthetic by intradermal injection and nerve blocking, and as an injection of the maxillary nerves for the extraction of a tooth.

A double thickness of moist gauze is placed over the entire face. This prevents the suture, hands and instruments from coming in contact with the skin. A speculum with solid blades is inserted. The conjunctival sac is irrigated with hexylresorcinol solution S. T. 37, diluted with 3 or 4 parts of water. Epinephrine is dropped into the eye to cause blanching of the conjunctiva.

OPERATION

A horizontal incision from 1.5 to 2 cm. long and 5 mm. above the limbus is made in the conjunctiva (*a* in the illustration) with small blunt pointed scissors. In cases complicated by glaucoma, where a Lagrange operation is indicated, it is better to make the horizontal incision from 7 to 8 mm. above the limbus. The wide flap is less likely to be followed by separation of the wound. The conjunctival flap with the episcleral tissue is dissected downward to the limbus and extensions are made on each side so as to expose the upper two-fifths of the circumference. If the hemorrhage is troublesome, a small pledget of cotton saturated with epinephrine is placed in the pocket. A mattress suture of 000 black silk in a small round full curve needle is now placed in the center of the edges of the conjunctival wound (*b*). The thread is drawn to each side, forming large loops, and a single knot is made. As the eyeball has not been opened, this can be done safely and easily. One also has definite information as to the behavior of the patient for the rest of the operation. Should he prove to be a "squeezer," the orbicularis muscle may be injected as suggested by Ván Lint, or a canthotomy performed. This is necessary in only a few cases.



Details of pocket flap.

The rest of the operation, which includes the opening into the globe and the removal of the lens, is done in a sterile field. The possibility of an infection following this method (either at the time of operation or postoperatively), when compared to the opening of the eye with the classic incision at the limbus, is reduced to a minimum. The operator, standing at the patient's head, holds the flap at the temporal portion with a pair of anatomic forceps. The point of a slender, tapering knife is placed beneath the conjunctiva in the pocket on the temporal side. The knife is held in the right hand when operating on the right eye and in the left hand for the left eye. The puncture is made at the limbus as in the ordinary extraction. The handle of the knife is depressed, and the counterpuncture is made directly opposite. Fixation is secured by holding the conjunctival flap. The forceps are transferred to the nasal part of the flap, which is then turned down over the cornea and away from the point of the knife, thus avoiding the danger of a buttonhole in the conjunctiva (*c*). The incision includes the upper two-fifths of the limbus. The anterior chamber is not evacuated until the incision is nearly completed. The taper of the knife and the conjunctiva overlapping the puncture and the counterpuncture prevent the escape of aqueous. By making a long bevel at the upper portion of the incision so as to include the sclera, a Lagrange operation may also be performed, if indicated.

If the iris is rigid, the sphincter is cut, or if it tends to prolapse, a small iridectomy is made. The anterior capsule is removed with forceps, and the cataract is expressed in the usual way by the application of pressure with a blunt spoon below at the limbus, the flap being held forward and up by the forceps (*d*). This maneuver elongates the globe, separates the wound edges, thus allowing easy extraction of the lens, and tends to prevent loss of vitreous. Any blood or cortex in the anterior chamber is removed by irrigation with Locke's solution or physiologic solution of sodium chloride. Should vitreous appear, the ends of the suture are drawn tight and the wound is immediately closed (*e*), thus preventing any loss. Irrigation is usually done before the suture is tied but may be done afterward, if necessary. Replacement of the iris can be done either before or after tying, by means of a spatula inserted on the opposite side of the central suture. If the patient has difficulty in looking down, or is unruly, or if the conjunctival flap is very thin and apt to be torn, perfect fixation can be secured by a suture in the superior rectus muscle. No assistant is employed during the operation except to hold the suture.

A light dressing is put over both eyes and a shield over the one that is operated on. The patient may sit up with a back rest. Iris prolapse from turning in bed, vomiting or postoperative delirium is not to be feared, as the wound is closed by the tight suture. If the iris is caught in the wound, this iris inclusion serves as a preventive against glaucoma.

Daljang Singh Khana,[17] who performs intracapsular extractions without iridectomy, advises the patient to sit up and not lie down for six hours, in order to guard against iris prolapse. He states that in the prone position the aqueous collects in the anterior chamber and makes the iris float upward, and as the wall is weak at the incision, the pressure all round the iris tends to bulge it out at the base into the incision and thus favors prolapse. In the sitting position, the aqueous fills the anterior chamber from below and its level rise is gradual; thus there is fluid on both sides of the iris, which hangs like a vertical curtain.

The next morning the eye is dressed, 1 per cent atropine is instilled, the bandage is replaced and the patient is allowed to sit up in a chair. On the second day 1 per cent atropine is used twice and the eye that was not operated on is left uncovered. All dressings are removed on the fourth or fifth day. The suture is easily removed at any time between the fifth and the ninth day. Patients are allowed to leave the hospital on the third to the seventh day, depending on the distance to their homes. Several patients have had the two eyes operated on at the same time.

In old persons with atrophic conjunctiva, the flap may be torn as the result of traction or the insertion of the needle. Fixation of the eye with a suture in the superior rectus muscle will avoid the former and the use of a round needle will prevent the latter complication. In eyes with shallow anterior chambers, the flap may be buttonholed because of the counterpuncture being made too far forward. The conjunctival flap should be dissected to the limbus. To indicate the exit of the knife, a shallow nick may be made in the sclera. In the earlier cases, my tendency was to make the incision rather far back in the sclera, as in the Lagrange operation. More bleeding occurs with this incision and there is danger of cutting the iris, thus making an iridectomy simultaneously. In shallow anterior chambers this may be almost unavoidable, but it is an advantage as the lens is more easily delivered, and the combined extraction is safer than the simple.

Most of the patients (80 per cent) went home in a week or less. Those who lived at a distance or were handicapped by having only one eye were kept longer. Many left the hospital on the second day with safety, as a result of the tight union of the sutured flap.

This operation is the application of the general surgical principle that, unless drainage is indicated, tight closure of a wound by layers of tissue is to be made. It is not to be confused with the ordinary sutured conjunctival flap described by Williams, Wurdemann, Kalt, Verhoeff, Elschnig and others, as in these methods the angles of the wound are open and not protected by conjunctiva.

RESULTS

I have done the pocket flap operation on 196 eyes. Fifty-two of the operations were reported in a previous paper.[12] Ninety-nine of the patients were men and 97 were women. The right eye was operated on 96 times and the left eye 100 times. The simple extraction was done 114 times, the combined operation 82 times.

TABLE 1.—AGES

Ages	Cases
30 to 40	5
40 to 50	12
50 to 60	36
60 to 70	63
70 to 80	61
80 to 90	17
95	1
96	1
Total	196

The ages by decades were as given in Table 1.

The days in the hospital are given in Table 2; 156 patients (80 per cent) were in the hospital seven days or less.

TABLE 2.—DAYS IN HOSPITAL

Days	Cases	Days	Cases
1½	3	8	9
2	10	9	3
3	34	10	5
4	41	11	2
5	17	12	5
6	28	13	5

		16	2
Seven days or less..	156	17	1
		18	2
		19	1
		31	1
		More than seven days	40

The astigmatism was as given in Table 3.

Glaucoma was present in ten cases. The vision was as follows: 5/4, two; 5/5, one; 5/6, one; 5/7, one; 5/9, one; nil, four.

There were six patients with diabetes. The vision obtained was as follows: 5/6, one; 5/12, two; 5/9, one; nil, two.

TABLE 3.—ASTIGMATISM

Diopters	Cases
None	12
0 to 1	30
1 to 2	56
2 to 3	39
3 to 4	29
4 to 5	8
5 to 6	2
8 to 9	2
12	1
Unknown	16
Total	196

Among the 196 cases, 11 were excluded as there was light perception only, with faulty projection, and the operation was not justified except for cosmetic reasons, or in the hope that some slight vision might be obtained.

The complications in the eleven cases not included in estimating vision, but in which good operative results were obtained, was as follows: glaucoma, four; detachment, one; diabetes, two; optic atrophy, three; intraocular foreign body, one.

TABLE 4.—VISION

5/22	1	Optic atrophy
5/30	1	Leukoma of cornea
5/50	1	Vitreous changes
Lost eye	3	
Unknown	3	
Total	185	

The vision was as given in Table 4.

In this series of 185 extractions, 174 patients, or 94 per cent, obtained vision equal to 5/12 or better. Among the latter, normal vision of 5/5 was present in 118 cases, or 63.7 per cent. The vision of three patients is unknown. Owing to their physical condition and distance of residence, they did not return for visual tests. One, aged 96, had sufficient vision to recognize persons; the second had high myopia; the third, aged 84, had choroidal changes. The latter had vision of 5/9 in the other eye following a previous extraction. The patient with 5/50 vision had vitreous opacities with posterior synechia due to a severe iridocyclitis one year previous.

COMPLICATIONS

In this series, three eyes were lost. A choroidal hemorrhage occurred on the fourth day in a myopic eye. This eye was later removed on account of pain due to increased tension. The wound remained tight and there was no leakage of blood. This demonstrates the firmness of the union.

Iridocyclitis caused the loss of two eyes. In one patient, a woman, aged 84, the flap was buttonholed or torn. An iris prolapse occurred through this tear as in the ordinary limbal incision. An iridocyclitis developed on the ninth day, resulting in loss of vision. This could have been prevented had an iridectomy been made, and this complication would not have occurred had there been a perfect flap; therefore it should not be classed as a pocket flap operation. A second case was in a woman, aged 78, who had diabetes. The operation on her other eye was successful.

There were five cases of slight subconjunctival iris prolapse.

Two cases of secondary glaucoma developed. These quieted down with resulting good vision.

In twenty-seven cases, a secondary cataract was divided, with improvement of vision.

In the entire series, vitreous presented twelve times. Owing to the immediate closure of the wound by the suture there was an actual loss in only five cases. In four of these, the lens was extracted with the loop.

Vision in cases in which vitreous appeared or was lost was as follows: 5/4, three; 5/5, two; 5/7, three; 5/9, one; 5/15, one; nil, two (glaucoma); total, 12.

DISADVANTAGES

There are two disadvantages to this operation. The first, suggested by Crisp,[18] is a lack of visibility in making the incision. This is more theoretical than real, as the flap can be manipulated so that there is no difficulty in making the puncture and counterpuncture. The second is that more hemorrhage occurs than in the ordinary incision. As the wound is closed by the suture, this blood goes into the anterior chamber rather than into the conjunctival sac. This hyphema is of no significance and clears up in a few days. Other objections, such as the length of time of the operation and the difficulty of removing the silk, could be raised against any sutured incision. The time is well spent if five minutes longer in the operating room will save the patient five days in the hospital. The removal of the suture from the eye does not involve any difficulties.

ADVANTAGES

The advantages of the pocket flap operation are as follows:

1. It offers the least possible chance for infection, as the operation is performed in a sterile field quite separate from the conjunctival sac.
2. With the use of the conjunctival flap as a means of fixation there is less danger of vitreous prolapse, as the traction on the flap causes an elongation of the eyeball and a separation of the edges of the wound; thus the lens is more easily expressed.
3. The suture may at any time be drawn tight to prevent vitreous escape.
4. The insertion of the suture previous to the making of the incision is done with safety. If the patient shows evidence of being a "squeezer," a canthotomy may be done or a suture may be placed in the superior rectus muscle in order to obtain fixation of the eye.
5. In case there is increased tension and a Lagrange operation is advisable, both an extraction and a sclerectomy may be done.
6. Healing takes place in a few hours, the patient may sit up the same day, and he may walk around with the eye covered the second day.
7. As the cornea is not cut, there is no danger of epithelium growing into the wound. In cases in which the incision had been made at the limbus or in the cornea, I have seen a patient with an ununited wound up to thirteen days.
8. After using a sutured pocket flap, the surgeon has the satisfaction of knowing that the patient is practically out of danger of prolapse and infection and that healing will take place immediately. There are several cases in this series in which the eye would have been lost if the large flap had not been used.
9. The vision in uncomplicated cases is as good as or better than that obtained by the small flap incision, as there is less astigmatism in the majority of cases and less striped keratitis.
10. Nausea and vomiting after cataract extraction are without serious consequences, as the sutured flap is a positive safeguard against iris prolapse. Law[19] has collected from Moorfields 141 cases of cataract extraction with vomiting in fifteen. There were ill effects in five of these and actual iris prolapse in two cases.
11. Should postoperative delirium occur, a sutured conjunctiva is a factor of great advantage as there is slight risk of a ruptured wound. In my experience, delirium has occurred but once in 800 operations.
12. A prolonged confinement in bed is not only uncomfortable to old persons but also subjects them to the danger of hypostatic congestion. With the sutured flap, this possibility is en-

tirely avoided, as the patient may with safety sit up immediately after operation.

LARYNGEAL EMERGENCIES IN INFANTS AND CHILDREN*

Kenneth A. Phelps, M.D.
Minneapolis

OBSTRUCTION of the larynx is an emergency. The degree of the emergency depends upon the extent and suddenness of the obstruction. There are instances where complete obstruction develops so quickly that death occurs before any medical aid can be secured. In any case, treatment should be immediate upon the establishment of the diagnosis. The nature of the obstruction determines the therapeutic procedure, as all cases of acute laryngeal obstruction should not be treated in the same routine manner.

The etiology of acute laryngeal obstruction was clarified enormously by the discovery of bacteria. Differentiation, particularly of lesions due to diphtheria infection, made a more definite classification possible. The next great advance was the invention of the direct laryngoscope. By its use, we are able to examine the larynx of a child suffering from laryngeal symptoms. By direct vision we are enabled to locate the point of obstruction, whether sub- or supraglottic. We can see a membrane, the motility of the vocal cords, the presence of secretion, edema, foreign bodies, or congenital defects. I know of but few contraindications to a direct laryngoscopic examination. I have performed it in many homes without difficulty, for it is not necessary that the patient be in a hospital for this examination. With such an examination there should be very little misunderstanding concerning the etiology of acute laryngeal obstruction. But that such is not the case is demonstrated by the persistence in textbooks on both pediatrics and laryngology in retaining the outworn terms "spasmodic croup," "false croup," "thymic croup," as synonyms of acute laryngitis or laryngismus stridulus. Coakley's textbook, published in 1930, states (page 587) "in infants no examination of the larynx can be made owing to the age of the patient," and again (page 494) "it is seldom possible to examine the larynx of a child." Richards[1] asserts, "Called to the home in a case of sudden and severe obstruction, the laryngologist must of necessity rely on tracheotomy or indirect intubation," implying that laryngoscopy cannot be satisfactorily performed in a home.

---

*Read before the Minnesota Academy of Ophthalmology and Otolaryngology, April 10, 1931.

Acute laryngeal obstruction in children may be classified as follows:

1. Congenital malformations
    a. Webs
    b. Absent tracheal rings or collapse of trachea
    c. Exaggerated infantile larynx with collapse (stridor)
. Birth injuries
    a. Dislocations
    b. Paralysis
3. Edema
    a. Primary
        1. Angioneurotic
    b. Secondary
        1. To lesions in the neighboring structures
        2. To general diseases
        3. Post-bronchoscopic
4. Inflammations
    a. Non-membranous
        1. Acute laryngitis, non-streptococcic
        2. Acute laryngitis, streptococcic
    b. Membranous
        1. Diphtheritic
        2. Non-diphtheritic
        3. Vincent infection
        4. Scleroma
        5. Crusts in laryngitis sicca
5. Neuroses
    a. Paralysis
        1. Central
        2. Peripheral
    b. Spasm
        1. Central
        2. Peripheral
6. Laryngismus stridulus
7. Foreign body
8. Tumor

Acute laryngeal obstruction, no matter what the cause, presents certain symptoms. Much valuable information may be gained from a comprehensive history, including information as to inoculation against diphtheria checked by the Schick test and by a general survey of the patient, including his temperature, pulse and respiration. If an X-ray is available, a plate should always be taken before laryngoscopy. Cultures and other laboratory findings should be obtained if time and facilities permit.

Inspiratory stridor is usually the first symptom observed. If extreme, it is accompanied by substernal retraction and the use of the accessory respiratory muscles. A high degree of restlessless soon occurs, and if allowed to continue long results in fatigue. Fatigue is a positive indication for immediate relief.

Cyanosis is not always present. It should not be the factor that determines interference. It may be present when an acute, complete obstruction occurs, or in the late stages of an incomplete obstruction. After cyanosis develops, the prognosis is less favorable.

Hoarseness is a valuable sign in determining the degree of obstruction or the presence of a membrane. Aphonia occurs at times.

Temperature indicates inflammation, while its absence suggests a foreign body, or laryngismus stridulus.

If none of these symptoms are severe, then no emergency exists and delay is justifiable. Should there be doubt, a direct laryngoscopy is indicated. This is much better than palpation, intubation or tracheotomy. Mirror laryngoscopy should be attempted when there is a chance of success, but the direct method can always be used.

The larynx in children has several peculiarities which should be understood before any examination is made. Some of these are responsible for the greater frequency of laryngeal emergencies in childhood.

The larynx is at a higher level in infants than in adults. The epiglottis is opposite the first cervical vertebra during late fetal life and the first year of infancy. It descends the distance of two vertebræ between the first and thirteenth years. The inferior margin of the cricoid cartilage is opposite the third vertebra at birth and descends to the level of the sixth cervical vertebra.[2]

The fact that the respiratory rate is higher in infants causes the respiratory function of the vocal cords to come into play more frequently. The relatively greater size of the tongue for sucking and the normal predominance of nasal breathing in infancy make mouth breathing more difficult for the infant than the adult.

At birth, one-half the glottic boundary is composed of vocal cord and one-half by the arytenoid vocal process. The process really projects into the cord and further reduces this soft fold. At the age of six the cord constitutes more than half the glottic boundary and at puberty two-thirds.

During the first three years the larynx grows rapidly; the next three years, less rapidly; and from six until puberty, quite gradually.

The larynx at birth is funnel shaped, the relation of a cross section of the glottis to that of the trachea being five to one. This funnel shape makes the importance of subglottic swelling much greater.

The cricoid plate tips backward as does the epiglottis, making the laryngeal orifice dorsal and at nearly a right angle to the axis of the trachea. The upper orifice is relatively narrow laterally. The cartilages are softer and make the possibility of collapse more likely.

The mucous membrane is more vascular and looser, especially in the subglottic region. The lymphatics are richer and there is much greater reflex irritability of the larynx.

Congenital anomalies of the larynx are not common. A lesion producing stenosis of the larynx at birth is usually incompatible with life. The most common symptom of congenital abnormality, in my experience, is the "congenital stridor." This condition is characterized by a croaking sound on inspiration without cyanosis or dyspnea. It is present at birth and usually disappears in the second year. The laryngoscopic picture is usually that of a curved, soft epiglottis with aryepiglottic folds so near together that they close the upper orifice of the larynx like a valve. This condition is thought to be purely anatomical by some, while others hold that it is due to an incoördination of the respiratory movements of the larynx and that it is central in origin. Those favoring the neurosis idea point to cases which develop after birth, and in which the stridor is absent while the baby sleeps.

CASE REPORTS

Case 1.—A baby, twelve months old, referred by Dr. Glenn Matchan, had breathed noisily since birth, this stridor having been inspiratory and not associated with hoarseness nor cyanosis. He was undernourished and nursed poorly. X-ray of the chest demonstrated a fairly large thymus. Direct laryngoscopy revealed the false cords and aryepiglottic folds pulled in at each inspiration. A bronchoscope was inserted and no tracheal compression found. A diagnosis of congenital stridor was made and a good prognosis given and the baby was taken home. Two months later he had some difficulty in feeding, butthis soon cleared up and he gained sixteen ounces in a few days. Then suddenly he had such severe laryngeal obstruction that death occurred before a doctor could reach him (thirty-five miles in the country).

Webs of the larynx occur in the newborn, but rarely cause enough obstruction to create an emergency. I can find no case recorded which required tracheotomy. This is the only fatal case of congenital stridor I have seen.

Inspiratory collapse of the esophago-tracheal party wall into the trachea occurs occasionally at birth and may be responsible for serious symptoms, as in the following case:

Case 2.—A newborn, referred by Dr. Rood Taylor, was a "blue baby" at birth and suffered from attacks of cyanosis at intervals. Two other children in this family had died at birth from congenital defects of various types. On examination the larynx seemed normal. The trachea closed on inspiration from a collapse of the party wall. No other abnormality was found. The infant lived but a few days. Autopsy showed a normal larynx. There were very few tracheal rings present and these were smaller than normal, thus accounting for the tracheal collapse.

Severe birth injuries involving the larynx are rare. I have had no experience with this condition.

Edema of the larynx in children from renal or cardiac disease is rare. The treatment of the underlying disease is of most importance. The laryngeal emergency is usually slow in development and adequate preparation for its treatment can be made. Puncture of the edematous area should be tried repeatedly, before tracheotomy is attempted.

Edema of angio-neurotic origin may occur in children. It may be the only sign of the disease, though more often there is a history of swelling of the lips, eyelids, or other parts. The family history should be investigated. The onset is usually sudden without preceding symptoms. The temperature is not elevated and death may occur before a physician arrives.

Laryngoscope examination shows a marked swelling of the arytenoids and aryepiglottic folds as well as of the epiglottis. The vocal cords are not involved. The swelling is whitish as a rule and does not give the appearance of serum below the mucosa. In texture it looks rather firm. Jackson recommends early tracheotomy as the edema is apt to persist. However, some cases do well after adrenalin is given subcutaneously as in the following case:

Case 3.—A boy, aged 6, was referred by Dr. F. J. Kucera. He felt perfectly well and was playing out doors when suddenly his breathing became difficult and he became cyanotic. There was no history of a foreign body. An injection of adrenalin was given by Dr. Kucera and the patient was hurried into the city (about ten miles). The child's stridor could be heard as he came down the hall to my office. A mirror examination was made and a marked edema of the epiglottis and arytenoids was seen. The child was so much better when he reached town that no tracheotomy was done. The edema cleared up in a few hours and no further attacks have occurred.

Post-bronchoscopic edema occurs in small children, even after careful use of the smallest tubes. I have had many such cases after the extraction of an organic foreign body, such as a peanut. As it is likely to develop within the first forty-eight hours, the patient should remain in the hospital for that length of time. If the foreign body has been in the bronchus any length of time, and a drowned lung is present, the postoperative laryngeal obstruction is not entirely edema, but may be due in part to lack of drainage of the thick secretion. In such a case I do a tracheotomy, but otherwise I have found intubation to be quite satisfactory. I allow the tube to remain for two or three days and then remove it. If obstruction persists after two extubations, I perform a tracheotomy.

The intubation is sufficient usually because there is no infection, but merely a traumatic swelling. I have found it necessary to follow intubation with tracheotomy in but a few cases.

Edema secondary to disease of the neighboring structures is a very serious condition. The patient is usually suffering from the toxemia of the original infection and is not able to withstand the added burden of respiratory obstruction. Relief must be prompt and radical measures are indicated early. The primary condition must be relieved if possible and if the secondary edema does not promptly subside, tracheotomy should be done. Intubation is not satisfactory, as the tube may be buried in the swollen tissue or it may be below the obstruction and thus be shut off just as the larynx was.

The following cases illustrate this type of edema:

Case 4.—A baby fourteen months old referred by Dr. M. Seham had had a sore throat associated with temperature and dysphagia for three weeks. These persisted and the baby lost considerable weight. Dr. Seham diagnosed retropharyngeal abscess one week before I saw the patient and advised its evacuation. The parents waited but finally brought the baby in. He was in bad shape, breathing with much difficulty and seemed to require emergency treatment. The abscess was incised with no anesthetic and a large amount of pus removed by suction, but the child stopped breathing. A bronchoscope was inserted at once and after several minutes respirations started. Oxygen was given for about six hours through the bronchoscope and finally the baby breathed fairly well. The next day an intubation tube was inserted and breathing was good for two and one-half days, after which cardiac failure resulted in death.

Case 5.—A boy, seven years of age, referred by Dr. E. D. Anderson, had a sudden attack of sore throat with marked malaise and temperature of 101 degrees. He was very toxic from the onset of his illness. The cervical glands on the right side became involved and one week later a swelling appeared in the region posterior to the right tonsillar fossa. This swelling became soft and fluctuant, so it seemed advisable to drain the abscess. Under gas anesthesia it was incised and suction used. Respirations became labored and it was necessary to use artificial respiration for about three minutes before breathing became natural. A tracheotomy was done to prevent possible recurrence of respiratory obstruction. Recovery was normal, with the exception of a persistently contracted right pupil, and a temporary paralysis of the right half of the palate.

Case 6.—An eight year old girl, referred by Dr. N. O. Pearce, had always been unusually healthy, but was suffering from a mild sore throat of twelve hours duration. Early the next morning she awoke on account of marked dyspnea. She became cyanotic and seemed to be in an alarming condition. She appeared very toxic, her temperature was 104 degrees and there was an acetone odor to her breath. A direct laryngoscopic examination was done at home and an enormously swollen epiglottis and very acutely inflamed lingual tonsils were seen. She was sent to the hospital and preparations made to perform a tracheotomy if necessary. Her general condition improved rapidly after she was given fluids, and her local laryngeal symptoms subsided in about three days. A stiff neck persisted for nearly two weeks, when complete recovery resulted.

Edema from abscess of the larynx is not uncommon in infancy, according to Jackson.[3] The laryngoscopic picture of acute inflammation, plus swelling, is quite definite. McIntosh and Nichol[4] report five cases of abscess of the larynx in infants, and state that laryngoscopy was of no value in localizing the lesion. All cases were opened externally. In one case the abscess was found during a tracheotomy. Aphonia was present. This group of cases is very interesting, but I am at a loss to understand how a larynx, obstructed to such a degree, could show nothing on laryngoscopy.

Abscess of the larynx results frequently from the use of X-ray or radium in treating papillomata. Overexposure produces necrosis of the laryngeal cartilages and abscess results.

Inflammation.—Acute laryngitis in children is frequently quite different from the same condition in adults, largely because the anatomical peculiarities above described predispose to the production of spasm. It is associated with dyspnea, frequently of sudden onset and occurring, usually, at night. The child goes to bed feeling well except for a mild coryza and awakens in an alarming attack of laryngeal obstruction. This is what most people mean by "croup," which the textbooks insist upon calling "true croup." The obstruction may be both expiratory and inspiratory and retraction is present in varying degrees as well as cyanosis. There is hoarseness but not aphonia and the temperature is elevated. Cough is usually present and of a metallic character.

The attack is over as a rule before a physician arrives. I have asked several pediatrists if they ever saw such an attack and usually they say, "When I was young I used to get out of bed and hurry to such a case, but I never got there in time. Now, I tell them to use steam inhalations and let me know what happens. I also tell them the attack will recur the next two nights."

These attacks are said to occur more frequently in children with infected tonsils and adenoids. If so, croup should be listed as an indication for tonsillectomy. It seems also that there is a constitutional type of child that is more susceptible to croup.

The etiology of croup is variable. It may be that when the child goes to bed the recumbent position, with a congested nose, tends to mouth breathing. This dries the secretion in the larynx and small crusts form on the mucous membrane causing irritation and some obstruction. The reaction to a foreign body is set up, leading to spasm. Such a spasm can be seen when inserting a laryngoscope to be a closure of the whole glottis, including the ventricular bands and the aryepiglottic folds. The action of the abductor muscles, being the most powerful in their action, predominates and the larynx is closed. Sometimes the pads below the true cords swell while the patient is lying down. This swelling may start a spasm of the larynx.

Acute laryngitis, with spasm, is the most common laryngeal emergency. It is a very alarming condition, but fortunately not serious, as a rule. In cases that do not clear up promptly a laryngoscopic examination should be made to make certain of the diagnosis.

Occasionally it is necessary to intubate for acute laryngitis with spasm. I have seen but one such case. This child, eight years of age (case 7), was intubated in the middle of the night after a laryngoscopy revealed no edema and no membrane. The tube was left in place thirty-six hours and no further trouble developed.

"Acute streptococcic laryngitis" is the common name given the more virulent type of laryngitis. This is the condition the older books call "non-membranous croup" and others call "infectious laryngotracheitis," "flu laryngitis," "phlegmonous laryngitis." This type of laryngitis occurs in measles, scarlet fever, small-pox and chicken-pox.

This condition simulates diphtheria in that there is marked prostration, fever, chills, convulsions, croupy cough, and frequently acidosis, hoarseness, dyspnea and cyanosis. The diagnosis can easily and quickly be made by direct laryngoscopy. The laryngoscopic picture is a fiery red mucous membrane with hemorrhagic spots in places. The lining is velvety and causes the tracheal rings to become invisible. Edema of the orifice of the larynx may be present so that the cords, themselves, cannot be seen. There is no membrane and but little secretion.

Such a patient has his laryngeal obstruction to contend with plus his general toxemia. Both need treatment, but the obstruction, if severe, should be the first to be relieved. I have tried intubation in these cases, but have not always been satisfied with the results as I have had to do a tracheotomy quite frequently. Hence, I usually recommend immediate tracheotomy as the best procedure. Immediately preceding tracheotomy, I usually insert a bronchoscope to render breathing safe during the operation and, also, to help locate the trachea more easily. Mosher's "life saver" tube may be used instead of the bronchoscope.

This condition is frequently confused with whooping cough and with the laryngotracheitis of a vegetable foreign body. The X-ray usually will establish the diagnosis of a non-opaque foreign body.

Case 8.—A child referred by Dr. Siperstein had developed sudden laryngeal obstruction during the progress of a cold and sore throat. He had been immunized against diphtheria. Laryngoscopy showed no foreign body, but a red swollen larynx with a dirty grey exudate. Intubation was performed, with recovery in about one week.

Case 9.—A boy, aged 6, referred by Dr. Wilder, had had a sore throat and cold for twenty-four hours. During the night sudden dyspnea and dysphagia developed and he breathed noisily. At examination the child seemed very toxic, his temperature was 104 degrees, and his breath had an acetone odor. Laryngoscopy showed marked edema of the epiglottis, but the cords were not involved. Steam inhalations with some oxygen and cold packs were prescribed and the next day the larynx was better, but pleurisy developed and later empyema. Recovery eventually occurred.

Case 10.—A boy, aged 2, referred by Dr. E. D. Anderson, developed laryngeal obstruction during an attack of measles. Intubation was performed which gave him relief as long as the tube remained in place. He coughed out the tube on six different occasions, so a tracheotomy was performed, the bronchoscope being inserted as a preliminary safety measure. A partial subglottic stenosis developed, making it necessary to be extremely cautious in decanalizing. After tightly corking the tracheotomy tube for forty-eight hours it was removed, but after a few days it had to be replaced. The stenosis was dilated several times and finally decanalizing was accomplished. A year later there was still a wheeze present on forced respiration. The trachea was again dilated and following this the boy has seemed comfortable.

Membranous Laryngitis.—Vincent's angina, scleroma and non-diphtheritic membranous laryngitis are very rare in children. A membranous condition can be diagnosed by laryngoscopy. Antidiphtheritic antitoxin should be given even though the child has been immunized for diphtheria and checked up with a Schick test. Bacterial studies for positive diagnosis can be made later.

If the condition requires immediate relief, the membrane should be aspirated and, if suction will remove it, no further relief may be needed. Hospitalization of such a case is absolutely necessary. At the Minneapolis General Hospital, considerable success has been obtained with suction, cutting down the number of intubations and tracheotomies to a marked degree.

Numerous physicians in the United States have abandoned intubation in laryngeal diphtheria. They believe intubation tends to produce stenosis of the larynx, which tracheotomy does not. I believe intubation has saved many lives and should be given a trial. The operation should be quickly and gently performed with the proper sized tubes. If extubation is not successful in three or four days, tracheotomy should be performed and the intubation tube removed.

Paralysis of the vocal cords is not common in young children. Its presence at birth due to injury to the inferior laryngeal nerve is reported. The more common causes are diphtheria and poliomyelitis and in some cases no cause can be determined. Children with a suddenly paralyzed cord breathe with an exceedingly loud stridor. This noise is very suggestive of a paralysis of a vocal cord. A snap-shot diagnosis might be made when this characteristic noise is observed.

Case 11.—A baby four months of age, referred by Dr. L. F. Richdorf, suddenly developed very noisy breathing. He had some elevation of temperature but his color was quite good and there was little substernal retraction. There was no history of a foreign body and no membrane was seen in the throat. I had recently seen two infants with almost the same type of breathing due to paralysis of one vocal cord and made a tentative diagnosis of a similar condition in this case. Laryngoscopy confirmed this opinion. The next day X-ray showed a pneumonia of the superior lobe on the right which explained the paralysis of the right vocal cord. Recovery was complete.

This type of case tends to clear up in time and usually no emergency treatment is needed, but the symptoms are so alarming that laryngoscopy is indicated for diagnosis.

A case of spasm of the glottis at birth due to intracranial hemorrhage was reported by Monro,[5] but no laryngoscopic examination was made and intubation gave no relief. Bilateral spasm produces a complete but not permanent closure of the glottis. Bilateral paralysis is permanent but does not produce a complete closure of the glottis. Spasm due to inflammation has already been considered. Spasm due to foreign body or the passing of a laryngoscope will be considered later.

Laryngismus stridulus is a form of laryngeal stridor in children of sudden onset without temperature or previous laryngeal symptoms and no malaise nor prostration. It appears usually between the ages of four months and two years. There are twice as many boys affected as girls.

As a rule, laryngismus stridulus occurs in feeble children, those with tetany, rickets or malnutrition. The onset is sudden, usually at night. The lightest cases are characterized by simple sudden stoppage of breath, ending with a deep, long drawn out and often loud inspiration. This condition is sometimes called breath-holding.

In severe cases inspirations due to glottic narrowing are audible at the onset, become more marked as the stenosis increases, and finally end in a cessation of breathing. Pallor and cyanosis rapidly develop, sweating appears, and finally unconsciousness. Convulsions may occur. Death within a few seconds from suffocation or cardiac paralysis does occasionally, though rarely, take place. Otherwise the attack ends with an inspiration in which a high degree of laryngeal stenosis is still evident. Successive inspirations become easier and longer in reverse order to the onset of the attack.

This condition is considered by most authorities in pediatrics to be a spasm, but St. Clair Thompson's latest book and Jackson's latest book both state that laryngismus stridulus is not a spasm, but a collapse of the feeble tissues at the vestibule of the larynx. Thompson describes the attack as due to the child attempting to breathe through its obstructed nose until it becomes half asphyxiated and then, due to the air hunger, a sudden deep inspiration is taken. As the diaphragm descends with extra force and the glottis does not open, the soft parts are sucked together before the in-rushing air current. As further efforts to breathe are made, the blood becomes more venous until the carbon dioxide stimulates the respiratory center and the glottis opens, ending the attack.

Riese[6] believes the posticus muscles have a nerve supply from the sympathetic system. He refers to Onaidis' anatomical work and gives other reasons for this belief. Laryngismus stridulus, in his opinion, is due to a paresis of this sympathetic nervous supply and is not a spasm of the adductor muscles. He reports cases which have responded to the use of pituitary extract and believes this supports his view.

Jackson states, "The laryngoscopic appearance is typical. The mucosa is pale and distinctly non-inflammatory. At inspiration, the upper laryngeal margin is drawn in and the cords draw together and separate but slightly at expiration. Insertion of a bronchoscope stops the stridor and tracheotomy is not indicated."

Treatment of this condition during the attack would vary according to the accepted theory of its cause. During the interval between attacks the general condition, such as rickets, tetany, diseased tonsils and adenoids, gastrointestinal irregularity or parasites should be corrected.

If the attack is considered a spasm, antispasmodics are advised and the Germans recommend hedonal by rectum, which affects the breathing centers, powerfully reducing the overexcitability. Others use chloral, bromide, chloroform, etc.

If the attack is considered a collapse, respiratory stimulants should be used such as cold water dashed into the face, smelling salts to stimulate the nasal mucous membrane and the maneuver of pulling the tongue forward.

Case 12.—A child one year of age, referred by Dr. C. L. Rodgers, had a sudden laryngeal obstruction occurring about midnight, which did not clear up promptly. The larynx was examined at home by the direct method and laryngismus stridulus diagnosed. Intubation was required, which had to be repeated about twelve times during twelve days. Bronchoscopy was negative as was the chest X-ray. Insertion of the bronchoscope did not stop the attacks. A culture proved negative. On the thirteenth day the tube was again coughed up and this time breathing was quiet. Recovery resulted.

A foreign body lodged in the larynx is not common. In two hundred and fifty proven cases of foreign body in the air or food passages, I have had but eight in which the foreign body lodged in the larynx, and, of these, five were in children. Many patients with a foreign body in the bronchus have laryngeal symptoms caused by the passage of the foreign body, or by digital or instrumental trauma in attempts to remove it, or by trauma due to the foreign body bouncing in the trachea and hitting the glottis from below. Several of my patients had been given diphtheria antitoxin before the diagnosis of foreign body was made.

The presence of a foreign body should be considered as a possibility in all children whose laryngeal symptoms develop suddenly and do not disappear as is usual in croup or laryngismus stridulus. If the symptoms are so severe that some treatment is necessary, intubation by the indirect method would be unwise, as inserting the tube might result in more trouble. Inspection of the larynx will show the foreign body and its removal can be accomplished by the direct method. The resulting trauma can be appropriately treated if necessary.

Case 13.—I recently saw a child a year old, who was left in the care of her five year old sister. In the afternoon she was taken out of doors in the cold and during the night, about 2 a. m., she became "croupy." A doctor was called who prescribed steam and the baby was better the next day, but not well. Another doctor from the same clinic saw the baby and diagnosed bronchitis. A day or so later a third doctor saw the child and diagnosed asthma. An X-ray of the chest was taken and, at the top of the film, a safety pin was seen in the larynx.

Case 14.—A baby one year old was referred by Dr. Schultz with symptoms of laryngeal diphtheria for which treatment was carried out ten days. X-ray revealed a safety pin in the baby's larynx.

A papilloma is the tumor commonly found in the larynx of an infant. This may cause all the symptoms of severe laryngeal obstruction. After the diagnosis is made, if emergency exists, a tracheotomy is indicated as the tumors have to be removed later and this cannot be done safely with intubation.

Tracheotomy alone may cure some cases of papilloma.

Case 15.—A patient of Dr. E. H. Parker's had a tracheotomy at the age of two with no further treatment. The tube was worn for fifteen years with but one or two changes. Her voice became normal and respiration was normal with the tube corked, but the mother would not consent to its removal. Finally it was removed and a plastic operation done to close the fistula, which was successful. The larynx is perfectly normal.

Epulation may cure others. In one case treatment was started at the age of two and one-half years. There had been hoarseness since birth, cough and attacks of cyanosis on exertion. Eleven operations were performed over a period of two years, resulting in a clear voice but low in pitch. There has been no recurrence in the past six years.

Fulguration seems to help others. Radium is of value but tends to produce necrosis of the laryngeal cartilages and may lead to abscess of the larynx or an esophagotracheal fistula.

Cure in some instances does not seem possible. A patient thirty-three years of age, referred by Dr. Nathanson, wore a tracheotomy tube thirty-one years. The larynx is still full of papillomata. Operations at ranging intervals have been necessary all her life.

Other types of tumors such as cysts and angiomata occur rarely and the treatment varies according to the condition present.

Conclusion.—Direct laryngoscopy has made possible the accurate diagnosis of laryngeal conditions in infants. The older ideas have been clarified and treatment made more logical.

SPONTANEOUS PNEUMOTHORAX*

W. H. Long, M.D., and R. B. Bray, M.D.
Fargo, N. D.

OUR purpose is not to report a large number of unusual cases, not to advance any new theory as to its cause, nor to recommend any new procedure for its treatment. It is merely to present a condition which does occur frequently enough so that we should all see a few cases, and a condition which is easy to diagnose, if we will just keep it in mind.

Spontaneous pneumothorax means the accumulation of air in the pleural cavity from any internal cause. Tuberculosis is considered the cause in eighty to ninety per cent of the cases by most writers, the perforation of the visceral pleura resulting from the rupture of a subpleural tuberculous focus into the pleural cavity. The remaining ten to twenty per cent are the result of a variety of causes, some of which are—the rupture of an emphysematous bleb, the tearing of an adhesion during violent exercise, or a paroxysm of cough; or any pulmonary disease, as abscess, gangrene, infarction or emphysema, which can cause an erosion or rupture of the visceral pleura. Also, an esophageal growth may result in an ulceration through the mediastinal pleura, or a perforation may be caused in this location by a sharp pointed foreign body in the esophagus. Then there are a few cases for which no cause can be found. These are called idiopathic spontaneous pneumothorax. These patients usually recover promptly and no sequelæ follow. Most likely these so-called idiopathic cases are due to the rupture of small blebs, or the rupture of small superficial tubercles.

---

*Presented before the Northern Minnesota Medical Association at Hibbing, Minnesota, September 14, 1931.

A spontaneous pneumothorax may be partial or complete, and may remain simply an air filled cavity, or it may become associated with a serous, purulent, or hemorrhagic effusion. The effusions generally indicate the presence of some active pulmonary disease.

A pneumothorax is said to be open when the pleural sac communicates freely with the external air, either through a wound in the chest wall, or through a bronchus; closed when the opening becomes sealed and the accumulated air is gradually absorbed; or valvular when the opening permits air to enter during inspiration, but closes during expiration with the result that air accumulates under increasing pressure. This latter condition is spoken of as tension pneumothorax.

Our cases, which will be reported later, are eight in number, and have come to us during a period of five years. The fact that only two of these were associated with definite tuberculosis leads us to believe that in a general practice tuberculosis may be a lesser factor in the etiology of spontaneous pneumothorax than has been taught. And, quite naturally, the statistics garnered from hospitals and sanatoria would deal with abnormal percentages of tuberculous individuals.

The onset of a spontaneous pneumothorax is usually sudden, and characterized by a sharp pain on the affected side, which may extend up and out into the arms, and may extend down into the abdomen. This is followed by marked dyspnea, cyanosis, and the general symptoms of shock. If the collapse is the result of a preexisting tuberculosis, or other inflammatory disease, the onset may be insidious and the patient may not know when it happened. This is due to the presence of adhesions which prevent the lung from collapsing suddenly or completely.

On examination, the following signs are found: There is little or no motion with respiration on the affected side, and the intercostal spaces are obliterated. The heart is displaced away from the affected side. The liver may be greatly depressed when the right side in involved. The breath sounds and voice sounds are suppressed, or entirely absent. Tactile fremitus is absent or greatly diminished. About this time one begins to suspect a pleural effusion, but on percussion, instead of feeling and hearing a dull flat thud, one is surprised to hear a highly tympanitic note. If fluid is also present, there is a corresponding area of dullness in the base, which comes up to a definite horizontal level and changes with a change in position.

The roentgen examination, made by either fluoroscope or film, and better by both, confirms the diagnosis.

The duration of the disease depends on the underlying condition, and on the presence or absence of infection. The case without apparent cause, the idiopathic spontaneous pneumothorax, which is believed to be the result of a rupture of a small sub-pleural tubercle or emphysematous bleb, or the tearing of a small adhesion, usually clears up in from two weeks to two months. The duration, however, may be indefinite, and at least one case has been reported that was permanent. The prognosis in active tuberculous cases is naturally more serious, and in these cases it has the same significance as hemoptysis.

The treatment is a simple matter in most cases. Morphine may be required for the pain at onset, and shock, if present, is treated in the usual way. As it is necessary for the fistula to close before the lung can expand, the patient should be kept in bed and quiet. Cough should be controlled and deep inspirations should be avoided. The latter tend to aspirate more air or infectious material into the pleural cavity. To this end, the affected side should be strapped.

In valvular cases, when the air accumulates under increasing pressure, and dyspnea and cyanosis become increasingly severe, it is necessary to aspirate just enough to relieve the symptoms.

Bilateral involvement does occur and is rapidly fatal unless some of the air can be aspirated.

When fluid develops, aspirations should be delayed until the fistula has had time to close, unless it is producing pressure symptoms.

Case 1.—R. B. B., a bookkeeper, aged 59, was operated upon in February, 1921, for a ruptured duodenal ulcer. One month later he had to be operated upon again for the same trouble. In May, 1925, while walking down the street, he was taken with a sudden severe pain across the upper abdomen. The abdomen was rigid and, quite naturally, it was suspected that another duodenal ulcer had ruptured. His white count, however, was only 12,600. The following day it was lower and his general condition was better. Because of some confusing signs in his lungs he was taken to the fluoroscope, where a right pneumothorax was discovered. Recovery was uneventful. In 1928 he was brought into the hospital with an acute appendicitis. Before operation his lungs were fluoroscoped and appeared normal. The appendix was gangrenous and he died.

Case 2.—S. D. F., a farmer, aged 48, was referred to the clinic supposedly suffering from an acute cholecystitis. Thirty-six hours previously he was awakened at 4 a. m. by a feeling of great distress and oppression in the right chest. He could not take a full breath. Later he had pains across the lower chest, which radiated around both sides to the back. There was some waterbrash, but he ate well and felt better after eating. On examination the left chest was found immobile and the intercostal spaces obliterated. Breath sounds were distant and percussion hyperresonant.

The diagnosis of left spontaneous pneumothorax was confirmed by X-ray.

In going into the past history of this patient, it was learned that he had had a cough with occasional blood streaked sputum for the past three years, also frequent night sweats, which made one suspect tuberculosis as the likely cause, although the X-ray showed no active lesion, and no tubercle bacilli were found in five sputum examinations. A recent report from this man said that he was working steadily and the cough was about the same as before.

This case was especially interesting for two reasons: the attack came on while he was asleep and the pain was mostly on the right side and the pneumothorax was found on the left.

Case 3.—G. R., a male, clerk, twenty-five years of age, was working at his desk when seized by a sudden severe pain over the heart, referred into the left shoulder and arm and down into the left abdomen. It brought out a cold sweat and he felt nauseated. He was brought in and seen at the Clinic twenty minutes later. Lips and nails were cyanotic, and heart tones at the apex were barely audible. The left rectus muscle was boardlike. He was sent to the hospital as a coronary occlusion, which would have been an unusual accident in a person of his age. His temperature was 99, w.b.c. 11,300 and electrocardiogram normal. The latter was accepted with the tentative diagnosis because the characteristic changes in coronary occlusion are often not seen until the next day. The following morning the left chest was splinted, breath sounds distant, fremitus diminished and percussion note hyperresonant.

Diagnosis: Left pneumothorax, confirmed by X-ray.

X-ray after two weeks in bed showed only a small amount of air at the left apex.

X-ray after one month showed complete absorption. X-ray after four months, negative for tuberculosis, and he has been well since.

Case 4.—M. F. M., a farmer, aged 22, had had a sudden sharp pain in the left chest five days previously, while stooping over. He was in bed one day, and unable to work since the onset because of pain and inability to take a deep breath. On examination, the heart was found displaced to the right and the tones indistinct. The percussion note on the left was hyperresonant.

The X-ray showed a left pneumothorax, and healed tuberculosis in the right apex. He could not go into the hospital so was told to stay in bed one month at home and keep a temperature record. After one month he returned. He said he had been in bed just one day, but that he had done nothing requiring exertion.

The lungs were completely re-expanded, he had gained two and one-half pounds and there were no signs of active tuberculosis.

Case 5.—S. U., female, aged 38, a teacher, was sitting quietly in a chair after a leisurely walk when she was seized with a sudden sharp pain in the right chest. She came to the Clinic the next day. Breath sounds were distant and percussion hyperresonant over the right chest. No tactile or vocal fremitus were present, and the heart was displaced to the left.

X-ray showed a right pneumothorax. There was complete absorption of air after two weeks in bed.

X-ray three months later and again two years later showed no tuberculosis.

Case 6.—K. McK., a female, aged 27, a stenographer, had had an incipient tuberculosis in 1926 involving both apices. By March, 1930, the tuberculosis was thought to have been completely arrested. On jumping out of bed to close the window, she was taken with a quick sharp pain in the right chest. On examination the right chest was found immobile, the breath sounds distant, and percussion note hyperresonant.

X-ray showed a right pneumothorax and she was kept in bed three months.

X-ray taken one year later, in May, 1931, showed healed lesions in both apices.

Case 7.—R. D., a male, aged 16, student, seemed perfectly well, had a good appetite, was active and gaining weight until September 28, 1930, when he had a severe coughing spell, so severe that it left him faint and trembling. The next day he had another, but not quite so severe. On the third day he was awakened at 2 a. m. with a cough, followed by hemoptysis of about one-half pint of blood. Examination one-half hour later, hemorrhage had stopped, pulse 140, temperature 102. Over left chest there was no expansion, no breath sounds and percussion was tympanitic. The heart was markedly displaced to the right. Diagnosis was pulmonary tuberculosis, pulmonary hemorrhage and left spontaneous pneumothorax. He was kept flat on his back. The air began to be absorbed very rapidly and one week later he was moved to the hospital, where we intended to continue the pneumothorax artificially.

The X-ray showed lung completely re-expanded and a diffuse tuberculous infection throughout both lungs. He died two months later.

This case is unusual in that an advanced tuberculosis was ushered in by a pulmonary hemorrhage and a spontaneous pneumothorax, the latter most probably stopping the hemorrhage. There was no pleural effusion and no sign of any blood having escaped into the pleural cavity. The air was completely absorbed and the heart back to normal position at the end of one week.

Case 8.—P. B., a male, aged 21, bookkeeper, was taken with a sudden pain in the upper left chest and arm, after walking across the office floor. Breathing became short and fast and he could hardly talk. On examination, lips and finger nails were cyanotic, excursion of left chest was restricted, breath sounds were distant and percussion hyperresonant. The heart was displaced to the right.

An X-ray of the chest showed a left pneumothorax. He had had four similar previous attacks.

In 1928 he "flopped" a pole vault. The attack came on that evening.

January, 1929, he jumped over a snowbank and attack came on one hour later.

August, 1929, attack came on while walking down town and he had to be carried home.

November, 1929, attack came on while shaving and he had to be carried in to bed.

He saw no doctor after these first spells, although he says they were more severe than the last one. He stayed in bed one or two days, after which he noticed no dyspnea, but had to be careful about lifting or straining for a few days. This time he was kept in bed for two weeks, after which re-expansion of the lung was complete.

X-ray one year later showed normal lungs.

This case is interesting, not only because of the recurrences, but also because it illustrates the fact that an attack can come on several hours after the exciting cause.

While these case reports are not complete histories, they do contain the salient points. They show some of the conditions which can be confusing in the diagnosis, namely, cholecystitis, coronary occlusion, ruptured duodenal ulcer and pleurisy. They also show how comparatively simple the diagnosis is when this possibility is borne in mind.

The teaching that tuberculosis is the most common cause must certainly be respected, and an individual should not be dismissed upon recovery from the pneumothorax, but should be systematically followed for many months for further evidence of tuberculosis.

HEART DISEASE IN CHILDREN*

Joseph F. Borg, M.D.
Saint Paul

The increasing force with which our attention has been called to the rising importance of heart disease as a cause of death makes it seem well that we occasionally take inventory of our knowledge of the subject, that we miss no opportunity to halt the progress of this greatest contributor to mortality in man. In the years 1917 to 1925[1] the population of the country increased over 10 per cent, the deaths from heart disease doubled, and the deaths to which heart disease contributed increased 81 per cent. Comparative figures of accuracy are difficult to obtain but when it is realized that more than 25 per cent of this great mortality[4] is due to forms of heart disease originating in childhood it brings to us the importance of attacking this problem where first seen, and, more important, of instituting prophylactic measures.

While the great mortality from heart disease is in adult life, about 20 children per 100,000 from 5 to 19 years of age in the United States Registration area (comprising 37 states and 82 per cent of the population) die yearly of heart disease, which ranks third among the causes of death in this group. The lack of the dramatic element in this disease and the insidious nature of its onset and progress have tended to prevent the attention being paid to the problem which it deserves. However, through the activity of the American Heart Association and the formation of local organizations to increase interest in the work, there has been in the past few years an awakening to the fact that this problem must be met with the intelligence we have been giving to that of tuberculosis, a problem similar in many aspects.

GENERAL CONSIDERATIONS IN CHILDHOOD

There are certain general considerations regarding the heart in children which are well to bear in mind. The heart itself is relatively large normally. The apex beat up to the age of seven years is located in the fourth left intercostal space, so that its presence in the fifth space before this time is evidence of hypertrophy. Enlargement of the heart in children causes an early precordial bulging of the chest wall which so accommodates itself to pressure. Normal sinus arrhythmias are frequent, sometimes so marked as to make them difficult to tell from pathologic rhythms. Extrasystoles are infrequent in children in the first decade,[5] and when found are usually due to a toxic myocardium, or organic heart disease.

---

*Read before the Park Region District and County Medical Society, Fergus Falls, Minnesota, January 14, 1931.

Bradycardias may be normal or may represent such toxic myocardial effects as those of jaundice and diphtheria toxin, the effects of intra-cranial disease, or varying grades of heart block. The heart sounds in the first year are of the tick-tock type, not to be confused with the ominous import of such a sound in the failing adult heart. Murmurs of functional type are frequent, usually basal, soft and blowing in quality, but sometimes hard to differentiate from true pathologic murmurs.

CLASSIFICATION

Heart disease in childhood is rather simply classified as congenital and acquired. About 10 per cent fall into the group of congenital disease, or, as they usually actually are, congenital heart defects, which will be considered briefly.

CONGENITAL HEART DISEASE

Etiologically,[2] congenital heart disease may occur from : (1) abnormal development (patent interventricular septa, etc.); (2) fetal endocarditis (resulting in congenital stenosis, usually pulmonary); and (3) failure of normal prenatal orifices to close (as patent ductus arteriosus and foramen ovale). The examples mentioned comprise the great majority of conditions encountered, others being decidedly infrequent and seldom diagnosed. These are often combined with each other, the signs due to two or more lesions making diagnosis especially difficult, although the more important lesion usually is emphasized by its own signs and can be so identified.[3]

Patent foramen ovale, the most frequent, is clinically unimportant because it is rarely large enough to embarrass the heart unless associated with other more serious lesions. Patent interventricular septa are next in frequency, do not usually produce cyanosis and are characterized by a substernal thrill, loud rough murmur heard best to the left of the sternum and transmitted over the precordium and to the back, an accentuated pulmonic second sound, and a globular heart by X-ray. A good many of these patients have other associated congenital lesions. They often live to adult life but usually die early from endocarditis or decompensation.

Pulmonary stenosis, uncomplicated, is usually fatal during the first year, but when associated with patent interventricular septum, which helps to compensate for the pulmonary lesion, adult life may be reached. The average age at death is nine to twelve years and those which reach adult life tend to develop decompensation easily. They are characterized by cyanosis, clubbed fingers, systolic thrill over the second and third inter space to the left of the sternum, enlargement of the heart, especially to the right, a loud harsh basal systolic murmur, transmitted over the entire heart, and a weak or absent pulmonary second sound.

Patent ductus arteriosus is not often found alone, but when so occurring the prognosis is usually good. More often does it compensate for septal and pulmonary valve defects. It is characterized by a rough systolic thrill over the base of the heart and a loud rough murmur rising with systole, passing over into diastole and then diminishing, heard above the heart. The second pulmonic sound is accentuated.

The foregoing characteristics make it often possible to diagnose a lesion but often the combinations create great difficulties and only the fact that a defect exists can be recognized. There is little in the way of treatment available. The cyanotic child should be protected from exertion, should have plenty of rest, good hygiene, and effort should be made to avoid infection. It is well to prepare educationally for a sedentary type of occupation. There is little indicated medically but nitroglycerine is occasionally of value in the attacks of cyanosis to which many are subject.

ACQUIRED HEART DISEASE

With a few exceptions, the story of acquired heart disease in children is essentially that of rheumatic fever. Diphtheria toxin produces a severe toxic myocardial insufficiency, not infrequently fatal. The contrast between the severe degree of injury shown by the heart muscle and the fairly complete and permanent restitution of cardiac efficiency is most striking. This condition is preventable and practically never seen where sufficient antitoxin is given within the first thirty-six hours.

The cardiac sequelæ of scarlet fever have so many similarities to rheumatic heart disease that it is not unlikely that they have the same pathogenesis. Pathologically they are very much alike and occur in similar age periods with rheumatic disease.

The ulcerative endocarditis of various types of septicemias must be mentioned among the acquired types. Practically it is unimportant because it is a late manifestation of conditions which are nearly always fatal, and no known treatment affects its course, which is characterized by variable murmurs of endocardial origin and embolic phenomena. Subacute bacterial endocarditis, infrequently observed, has been thought by some to be etiologically identical to rheumatic carditis, and is probably not so invariably fatal as originally considered.

RHEUMATIC FEVER

It is, however, with the consideration of rheumatic fever that the most important field of cardiac disease in children is entered. Nearly 90 per cent of cardiac diseases is rheumatic in origin. Of these patients a considerable proportion die in childhood, and the rest constitute the bulk of adult heart disease up to the age of forty, a large proportion being crippled or killed within this period. To know rheumatic heart disease one must know rheumatic fever, because the heart condition is only one of the protean manifestations of this disease, characterized as it is by exudative and proliferative lesions of the serous membranes, sinuses, tonsils, joints, nervous system and heart. It is therefore just a phase of a disease which is seen in many forms. It is the most important phase because it is the most crippling, and occurs most frequently, it being definitely demonstrable that the heart is involved in 90 to 100 per cent of all cases of rheumatic fever.[6]

Since the onset of rheumatic heart disease, or carditis, is usually insidious, a knowledge of the other manifestations of rheumatic fever and tendency to remissions[20] will point out earlier the presence of this disease. This should lead to the important periodic observation for cardiac signs and especially for the signs of activity of the infection, and permit the institution of intelligent management.

These signs may be summarized as follows:

1. Polyarthritis: the well known migrating type of acute arthritis, affecting usually the larger joints, with extreme tenderness and good response to the coal tar derivatives. This is often the first manifestation, usually occurring before the age of ten.

2. Joint and growing pains: fleeting pains in various joints, or in the muscles, chiefly of the thigh or calf of the legs, or in the hamstrings just behind the knees.[8,9] They may be intermittent or persistent, and are not infrequently the earliest and only manifestations preceding cardiac involvement.

3. Tonsilitis: occurring in about 50 per cent of the cases and present as a first manifestation in 14.3 per cent of a series of 500 cases.[7]

4. Chorea: occurring in 42.8 per cent of the aforementioned series.

5. Rheumatic nodules: small rice-like bodies under the skin, especially over the bony prominences and joints. They are associated with other very severe manifestations, and occur in about 15 per cent of cases, which as a group show a high mortality.[7]

6. Upper respiratory infections and acute nephritis[10] may be included as manifestations.

These various manifestations, including the carditis, rarely occur under three years of age, usually from six to ten years, and have a marked tendency to recrudescence. The younger the patient the more the tendency, although a marked increase in the recurrences is found at puberty. The later the disease manifests itself the more likely that the recurrences will be widely separated and the development of heart signs will appear later.

OCCURRENCE

Contrary to what has frequently been supposed, the majority of children with rheumatic carditis come from moderately well-to-do homes. They do not live in an environment of dampness, and are not overcrowded in their habitations. They live chiefly in temperate climates, and only a very small proportion are from other than the white race (4.6 per cent in 500 cases).[7]

It is interesting to note that a series of studies of familial infection shows that in 29 per cent,[11] 36 per cent[12] and 50 per cent[13] of the families having rheumatic cardiac children, two or more children were found to have this disease. Also while about 10 per cent of those with rheumatic cardiac disease give no history of other manifestations of rheumatic fever, a high incidence of these symptoms can be found in the histories of the unaffected members of the family. Recognizing the marked similarity of many aspects of tuberculosis to those of rheumatic fever it is significant to point to a study by St. Lawrence, who in comparing the cases of each disease discovered in affected families found that 14.8 per cent of exposed individuals in rheumatic families were attacked by rheumatic fever and 14.6 per cent of those in tuberculous families were affected by some form of clinical tuberculosis. In view of the stress laid upon the importance of control of contacts in tuberculosis it is of more than passing interest to consider these observations.

ETIOLOGY

As to etiology it must be admitted that while no specific agent has yet been incriminated, the streptococcus is generally considered to be the cause. Numerous workers have isolated such an organism with varying success from blood and tissue cultures taken from rheumatic patients. Clawson[24] has been successful in 50 per cent of his cases, and also feels that there is much evidence pointing to the same etiology existing here as in subacute bacterial endocarditis, where the streptococcus is so regularly found.

CLINICAL FORMS

Rheumatic carditis occurs as a myocarditis, endocarditis, or pericarditis, often associated, but probably occurring in frequency in the order named. Repeated work has shown that the heart muscle is affected in practically all cases of rheumatic fever as demonstrated by electrocardiographic studies. Seham[14] has shown that after six months of age the normal mechanism is the same as in the adult, and that the child is subject to the same abnormalities. Among the changes found are an almost constant increase in the conduction time (P-R interval) which is unaffected by antirheumatic drugs, bundle branch and arborization changes, a great variety of changes in the S-T interval as lengthening of the S wave upward and convexity or concavity of the S-T interval, and changes in the T wave. Where any doubt exists as to myocardial involvement, the electrocardiogram is of great value. With the subsidence of the attack the myocardial phase usually recedes, but occasionally there may remain a myocarditis as demonstrated by precordial discomfort, persistent fever, persistent leukocytosis, anemia, anorexia, enlarged heart, relative valvular insufficiency or tachycardia.

Endocarditis, or rheumatic valvulitis as it is better called from its now recognized pathology, is not easily detected in its incipient stages where its physical signs are due to the valve deformity occasioned by swelling, and a variable murmur, systolic or presystolic, may be the only finding. Usually the mitral valve, less often the aortic, and infrequently the others are involved, and it is the cicatricial changes associated with the healing process occurring here and producing the typical clinical features of valve deformity, which may seriously embarrass the heart long after the active inflammatory process has subsided. These changes proceed at variable speeds, apparently depending on the extent of the valvulitis, and this accounts for the marked delay in appearance of the typical picture which embraces so large a portion of the cardiopaths in early adult life. The marked tendency to recurrence of rheumatic infection is seen here also and the multiple valve involvement is probably always due to multiple infection, the later ones of which are practically always the causes of decompensation when seen in children.

The typical valve lesion produced is stenosis of the mitral valve as the scarring progresses, it being relatively infrequent, as Cabot[15] has shown, to find an uncomplicated mitral insufficiency. The earliest signs are the loud sharp apical first tone, and the accentuated, reduplicated pulmonic second tone, with a soft transmitted apical systolic murmur. Later the typical presystolic or mid-diastolic murmur appears, associated with the characteristic outline as shown by the X-ray. The aortic valve usually develops an insufficiency as the lesion progresses, with its to and fro blowing basal systolic and diastolic murmurs (heard best as a rule over the second right interspace, less often under the sternum or as low as the fourth left space), the high pulse pressure, water hammer pulse, capillary pulsations, and Duroziez' sign. Aortic stenosis is more difficult to recognize and occurs much more often than it is diagnosed, the characteristic basal thrill, loud rough basal systolic murmur, and plateau pulse being infrequently combined as a clinical picture.

Pericarditis is less frequently seen. Before the age of five it is seldom rheumatic, being usually secondary to one of the acute exanthemata, typhoid, erysipelas, or other infection. After five years it is usually rheumatic, often associated with a severe pancarditis. It may be fibrinous, serous, or suppurative in type, associated with or without a palpable or audible friction rub at the base, and is often missed in diagnosis as it is overshadowed by other features of the disease. The rapidly widening percussion area, atelectasis of the base of the left lung, distant rapid heart sounds, marked substernal pain and orthopnea, as well as the friction rub which is pathognomonic, indicate the diagnosis. Chronic adhesive pericarditis may occur in children, and when advanced enough to produce signs of heart failure, is serious. The electrocardiogram is helpful in diagnosis, and cardiolysis may be of help in treatment.

SIGNS OF ACTIVITY

Recognizing the early appearance of heart involvement in rheumatic fever, and the tendency for the infection to persist in a low grade form for a long time, it is necessary to look for signs of activity of the infection, especially in the heart, that proper treatment may be pursued. Since these signs will be discussed later under the matter of treatment, they will not be further dealt with here except to state that their recognition as such may lead to the consideration of rheumatic fever in children where chronic infections of uncertain diagnosis have persisted.

IRREGULARITIES

Irregularities of the heart are infrequent in children, but any of those found in adults may also occur here. The practical absence of extrasystoles in the normal child[5] makes such an ordinary arrhythmia of adult life a more significant occurrence in childhood. The normal sinus arythmia is often so marked and difficult to interpret clinically that only the electrocardiogram will distinguish it from a rhythm with many extrasystoles or auricular fibrillation or flutter. The latter two are infrequent and nearly always associated with advanced and grave heart disease. Paroxysmal tachycardia, paroxysmal flutter, or paroxysmal auricular fibrillation are uncommon, the first occurring occasionally in later childhood, and the latter two being almost always a part of degenerative heart disease, which is seldom seen in early life.

TREATMENT

If the many similar aspects of tuberculosis and rheumatic fever would lead to a greater similarity in the general plan of treatment of these patients, there would undoubtedly be much less chronic heart disease left after the infection has been eliminated. There is no question but that a large number of these patients are permitted to resume activity before the infection has entirely subsided, and the failure of development of an adequate defense against the infection increases the tendency to recrudescences which are so characteristic of the condition. The disease must be treated as a chronic one, and Swift has found much better results in his series where the patients are kept in bed from two to three months or longer according to the persistence of signs of activity.

The common and alleviating use of salicylates and allied drugs in the acute stages of rheumatic fever makes the patients so comfortable that it serves to mask the presence of certain indications. It is apparently most useful in combating the exudative phenomena of the disease, as it is of no demonstrable value in chorea or carditis where the lesions are mainly proliferative.

The absence of any specific therapeutic agent for rheumatic fever makes it obvious that the treatment must be general and symptomatic. Good nursing care is essential and it is unnecessary to go into details which are common to all textbooks, to extol the virtues of rest, environment, nutrition, heliotherapy and others. The frequency of multiple infections in a family makes it seem wise that a careful technic of handling the patient, and advice to those exposed regarding the possibilities of danger, be stressed in management. The patient with active infection should be kept in bed until all signs of activity have subsided, even though this may mean many months. These signs are important to know and may be outlined as follows:

1. Fever. This is always to be considered a sign of activity, although other signs may be present without it. Since it is usually highest in those cases with exudative phenomena, it is nat-

urally most marked in those in which the coal tar derivatives are most comforting and efficient in alleviating the condition, best exemplified by the polyarthritis. The temperature falls often to normal under such therapy and it is a not uncommon mistake to permit a patient to resume activity while still under these drugs which are masking the picture of activity of infection from the symptomatic and febrile point of view. Therefore no patient should be considered afebrile until the temperature remains normal after the patient is free from the influence of such drugs. In certain instances the temperature will show an occasional rise at intervals of several days and this should not be ignored. At least ten days of normal temperature should be shown before considering the infection inactive from this angle.

2. Pains: Muscle, joint, and precordial pains are often an indication of activity, and should be so considered until proved otherwise. As in fever, the masking effect of the antirheumatic drugs is marked, and it is better to have had the patient off these drugs about two weeks, before these signs can be considered as gone.

3. Leukocytosis: Repeated leukocyte counts give valuable information as to activity. With subsidence of the infection, the counts gradually come down to normal, the curve of reduction following the curve of fever decline in a somewhat delayed manner. Any delay in the approach of leukocyte count to normal must be considered a sign of activity.

4. Anemia: Anemia being fairly constantly associated with activity should be carefully considered. As the infection subsides this should improve, although not infrequently the anemias which are associated with mitral stenosis are found to be most resistant to therapy, even in the absence of other signs of activity. Thus great caution should be exercised in regarding an infection as inactive where the anemia proves resistant to treatment.

5. Pulse response: The pulse rate should have returned to normal with subsidence of infection and a normal type of rhythm be present. The response to the usual exercise test will give valuable help in determining the heart's efficiency,[7] the return to a previous rate requiring more than three minutes being considered abnormal.

6. The child should show a normal gain in weight.

7. Signs of fatigability, lack of appetite, afternoon irritability, and restless or delayed sleep are often signs of activity and should be relieved before the infection can be considered inactive.

8. Signs of heart failure in children, as basal lung râles, congestion of the liver, dependent edema, cyanosis, etc., are practically always caused by an active rheumatic carditis.

After the activity has subsided a prescribed course of gradually increasing exercise should be worked out as well as possible. The child will usually show if it is being pushed too fast by the poor heart response to exercise and by the tendency to avoid exertion which distresses it and certain types of playing with other children which lead to undue fatigue. As convalescence proceeds the child will usually be able to pursue a normal course of living, with full myocardial compensation. Breaks in compensation, as stated, are nearly always due to lighting up of the infection,[19] and in such an event the treatment must be repeated.

In the acute stage drugs are never indicated except for symptomatic relief. Sodium salicylate still remains the most reliable of the safer products to control the joint symptoms. Where the carditis is the only manifestation the patient is often restless and as complete relaxation as possible should be secured. For this distress Tr. Opii, two to four drops every three hours in older children, is often very helpful. Digitalis[17] is contraindicated in the acute stages, probably acting as a toxin to the heart muscle. Serious accidents may occur from its use.

In that very small group of decompensated patients without active infection, the heart is always enormously enlarged as the result of repeated infections and the therapy is the same as that used in adults. Here digitalis is indicated but the patients are very refractory to treatment and the prognosis is decidedly bad as to life expectancy.

Since most of these children are of school age, the routine of their education imposes certain burdens which should be considered.[18] Their instructors should be acquainted with the problem. It is wiser that these children should be permitted to enter and leave school outside of the regular hours, and be excused from such exertions as gymnasium and fire drill. Many of them under close supervision can partake in athletics, but the competitive variety should be forbidden. Most of them require no special solicitude, but for those who do, it may prevent the lighting up of the infection which undue fatigue can precipitate. Adequate rest is just as essential as in tuberculosis.

The question of tonsillectomy has been very carefully studied.[1,21,22] There is little question that tonsillitis may be one of the manifestations of rheumatic fever, and as the tonsils are not the sole focus of the disease, their removal would not be expected to cure it. Nevertheless a tendency to frequent upper respiratory infections which is often eliminated by the removal of diseased tonsils may so reduce the resistance of the patients that the rheumatic fever lights up. Kaiser,[21] in an analysis of 48,000 school children, observed that the tonsillectomized child without previous rheumatic fever has a much better chance to escape the disease than the one with tonsils, and that scarlet fever, heart disease, and recurrent attacks of rheumatic fever are less common where the tonsils have been removed.

PROPHYLAXIS

While the prevention of rheumatic heart disease, a goal sought by the profession, is somewhat discouraging in the absence of control of the etiologic agent, there are certain observations which may be suggested as helping to aid this end:

1. Periodic examination of children. To this the parents must be educated, and emphasis must be laid on the importance of the pre-school age, before the child is seen by the school physician. The family physician is in the best position to guide such activity.
2. Removal of foci of infection in teeth, tonsils and sinuses. While authorities disagree on the problem of teeth removal in children, all are agreed that roentgenologically demonstrated root infection is adequate reason for such action. The intelligent coöperation of the dentist is necessary here. Demonstrable infection in the tonsils or sinuses indicates its removal, and the history of repeated attacks of tonsillitis reads its own verdict for tonsillectomy.
3. Adequate rest after infections. Detention in bed for several days after any acute infection and repeated later examinations will give assurance that the physical condition of the child is satisfactory before resuming activity.
4. Heliotherapy over long periods seems to definitely increase the resistance to infections. Significant may be the fact that the highest incidence of rheumatic fever occurs at the end of the winter months, and in the temperate climes.
5. The maintenance of satisfactory nutrition is of great importance in building up resistance to infection.

PROGNOSIS

Considering our experience with patients suffering from rheumatic carditis, about 75 per cent of them will be restored to a normal functional capacity on recovery. The rest represents patients with varying grades of compensation. The majority will be found to be held back by the presence of extra-cardiac foci of infections, occasionally by overweight conditions and toxic states as hyperthyroidism. The correction of these is usually sufficient to bring back compensation with fair reserve. Four to 5 per cent of the patients have low grade persisting rheumatic fever, must be kept in bed, and the outlook is decidedly bad. One to two per cent will be afebrile decompensated children who have had repeated rheumatic infections, who have failed to develop resistance to the infection, and in whom the outlook is unqualifiedly bad. Of rheumatic children up to the age of fifteen years, about 10 per cent will die in that period, usually of rheumatic heart disease. There are no known reliable figures on the outlook for the 75 per cent who recover functionally. However it is known that while many escape further infection and have not developed a sufficient or progressive enough degree of damage to later embarrass them, a great many others develop recurrences later, or show the effects of slow cicatrization of valve defects, and eventually prove the most substantial contributors to the group of heart patients below the age of forty. It is in this group that we hope to materially improve the prognosis through the control of rheumatic fever in children.

SUMMARY

The problem of heart disease in children opens up for us a means of attempting to alleviate much suffering, not only in children, but in early adult life.

Congenital heart defects cannot practically be prevented, and when seen are simply problems of management of activity and protection against infection.

Rheumatic heart disease is deserving of much study. It is felt that much of the crippling type of this disease may be prevented by adequate care while the infection is active, and it is urged that an attempt be made to so guide every patient through this stage and the later period of tendency to recrudescence so that further damage may be avoided.

THE TREATMENT OF RICKETS*

Olin W. Rowe, M.D.
Duluth

RICKETS offers a striking example of a comparatively large number of diseases that have undergone a marked modification during the last two decades. The cases of rickets encountered fifteen or twenty years ago were more florid than those seen today. Now the disease is usually of so mild a type that it is far more frequently overlooked than diagnosed and consequently a large number of cases are untreated.

It is not the purpose of this paper to discuss the diagnosis of rickets or to remind you of its almost universal presence when prophylactic measures are disregarded. Rather it is hoped to emphasize the necessity of treatment by recalling its frequency and again drawing your attention to its relationship to upper respiratory tract infections, its effect on the prognosis of such diseases as pneumonia and its remote influence on functional and organic disturbances of later life. The present treatment has been largely developed during the last decade.

No attempt will be made to discuss the treatment of rickets from a public health standpoint. As an economic problem it is of greatest interest to those dwelling in large cities. The disease, however, does exist in smaller communities and in the country, but to a far lesser extent. In some of the small cities in the territory encompassed by this society, industry is seemingly unable to solve the basic problem of continuous employment at an adequate wage. Consequently increasing demands will be made upon the medical profession for time, knowledge and even money to meet community health problems. Rickets is not the least of these problems. The fact that some localities are now treating rickets from a communal standpoint may have some significance for us.

---

*From the Pediatric Department, The Duluth Clinic, Duluth. Presented before the Northern Minnesota Medical Association at Hibbing, Minnesota, September 14, 1931.

PRENATAL CARE

In considering preventive measures from an individual standpoint, prenatal care has failed to offer the benefits expected. While a certain predisposition or susceptibility to rickets is recognized as having some relationship to faulty nutrition in the mother, experience does not lead us to believe that much can be expected from prenatal measures. It is true that nutritional disorders in the mother require consideration and the usual recognized measures should be taken to insure healthy babies of full term but more specific treatment has failed to produce striking results. Hess and Weinstock[1] gave expectant mothers cod liver oil the last two months of pregnancy without apparently affecting the incidence of rickets in their babies. Other measures such as the prenatal irradiations by ultra-violet light have also failed.

DIETARY TREATMENT

In considering the prevention and treatment of rickets from a dietary standpoint we have to bear in mind that milk, either human or animal, is the universal food for infants.

Human milk possesses antirachitic properties to a greater degree than any other food. The incidence of rickets among nursing infants is far less than in those fed on cow's milk. The reason for this is unknown, but it is agreed that it is not entirely due to its greater content of antirachitic vitamin. Human milk is not, however, to be considered a specific for either the prevention or the cure of rickets. We must remember that the vast increase in the incidence of rickets in the seventeenth century, a wave of such great proportions that it involved most of Europe and led to the formation in England of the commission headed by Glissen, occurred at a period when all babies were breast fed. The incidence of rickets of the present generation is indicated in a study by Hess[2] in New York, who showed that even well nourished breast fed babies of mothers on a generous and varied dietary developed rickets in about 33.3 per cent by March unless they received some specific therapy and in the course of the subsequent year at least 50 per cent showed definite signs. Similar observations have been recorded by other observers.

The lack of the complete protective property of breast milk has not been sufficiently recognized. This has led to the belief that the use of cod liver oil and other recognized specifics is unnecessary for the breast-fed child. Under present conditions all babies require protective therapy of some kind.

Mothers' milk may be made specifically antirachitic by irradiating the nursing mothers. Hess[3] and more recently Gerstenberger[4] have irradiated mothers with excellent results. The latter in two cases of non-healing rickets observed marked progress when this therapy was instituted. He was not able to achieve the same results by giving mothers cod liver oil.

Cow's milk contains a comparatively small amount of the antirachitic vitamin. This is not improved by modification, condensing or drying unless the specific factor is added. Neither is it possible to increase the antirachitic properties of milk by improving the hygienic conditions of the cow. Little difference is noted in the antirachitic titer of milk when the cows are exposed to sun or kept indoors, but it has been shown that cows exposed to ultra-violet rays from artificial sources elaborate the antirachitic factor and excrete it in the milk. The feeding of a pint of cod liver oil has been without success in increasing this factor. Hess[5] has recently reported encouraging results by feeding cows with irradiated yeast and viosterol. If this should prove practical on a universal scale, it would automatically supply the infant with the antirachitic vitamins.

The yolk of eggs furnishes a demonstrable amount of the antirachitic factor. Egg whites have no such protective value and even in small amounts may increase the intensity of the disorder.

The addition of cream and butter is thought to increase the protective value of diets. The amount of butter fat, however, necessary to appreciably increase the antirachitic factor must be regarded as having possibilities of introducing other nutritional disorders.

Fruit juices, cereals, and vegetables have no protective value.

The indirect use of the ultra-violet rays obtained by giving foods activated by sufficient exposures to produce the specific antirachitic factor is attractive. Milk, particularly dried milk, has been so treated for a number of years. Other foods, especially cereals, have also been activated. The amount of the specific factor in foods so treated is small. Therefore, the quantity required to produce satisfactory results is so large that such activated foods are advised only as adjuvants to other treatment.

An inadequate diet resulting in a subnormal gain may result in rickets. If the diet is suddenly increased to a point which results in a rapid gain in weight without a proportionate increase in length, rickets is likely to develop.

An adequate diet resulting in a normal rate of growth is the greatest protection that may be expected from a dietary standpoint.

HYGIENIC MEASURES

Measures usually included under the term "good hygiene" should not be neglected because of the beneficent effect upon the infant, but it is doubtful if any except sunlight have a pronounced effect on either the prevention or cure of rickets. Lack of exercise in a child that can not stand can be of little moment in the development of rickets. Massage and salt baths may increase the nutrition of the muscle. Fresh air, while desirable, is without specific effect. Out of door life in our latitude can not be expected to be of value if the atmosphere contains sufficient dust, smoke or moisture (fog) to exert a screening effect upon the sun's rays. Changes of climate are beneficial when they make the desirable solar rays more available.

DIFFICULTY IN EVALUATING SPECIFICS

We are fortunate in having several specific curative agents. Attempts to properly evaluate these are attended with many difficulties. Many factors have to be considered, as for example the rate of growth of the infant, the season of the year, the degree of coöperation of the mothers and the severity of the case. Other complicating factors are diarrhea, repeated upper respiratory tract infections, extreme feeding difficulties, anemia, enlarged spleen and the complicating porosis occasionally seen in children who have been bedridden. Premature infants and twins usually require intense treatment by two or more specific agents.

COD LIVER OIL

A consideration of the several specifics for rickets must give first place to cod liver oil. From the time that it was first used early in the eighteenth cenutry until recently its specificity has been frequently questioned and occasionally denied. Kassowitz,[6] an authority of his time, introduced the use of elementary phosphorus which he suspended in cod liver oil. He attributed his excellent results entirely to the phosphorus. Compere[7] has again recently raised the question as to the value of phosphorus combined with the oil. The conclusions of both men have been questioned by Hess,[8] who recognizes the calcification of the bone following the use of this drug but points to the failure of calcification of the proliferating cartilage.

That cod liver oil is today universally acknowledged as a specific is due probably first to Mellanby,[9] who, in the course of his experimental study of rickets in dogs, published roentgenograms which left no doubt that calcification of the epiphyses can be brought about by the administration of cod liver oil. Park and Howland[10] and others corroborated this work. In addition, other investigators have shown its favorable effect on the calcium and inorganic phosphorus of the blood.

The proper dosage of cod liver oil depends upon several factors, the most important of which is the rate of growth of the infant. As a preventive measure it may be given in five drop doses to a child of two weeks. This may be gradually increased so that at four months the child is taking one teaspoonful two or three times daily, depending upon the other antirachitic measures employed. As a curative agent larger doses are necessary. If indicated, a dessertspoonful two or three times daily may be given and is usually easily tolerated at the sixth month.

Like all specific remedies, cod liver oil may occasionally fail to prevent or cure rickets. Failures may be due to the refusal of the baby to take the oil. Such refusals are augmented by neurotic mothers who dislike the odor of the oil and make this apparent. Occasionally the oil is regurgitated. Perseverance for a week or two in either of these conditions usually results favorably. Failure to prevent rickets in breast fed babies is occasionally encountered. This may be due to too low dosage of cod liver oil but the low calcium and phosphorus content in mother's milk has to be considered in such cases. In the rare cases of frank rickets where partial failure follows the use of oil it is probably due to the impossibility of giving sufficient of the antirachitic factor. This condition is obviously easily handled by adding ergosterol to the oil, a combination usually necessary for premature infants and twins. Untoward results need not be feared as the toxic dose of ergosterol is approximately forty times the normal therapeutic dose.

Another possible factor in the failure of cod liver oil is the doubt thrown by Hess on the question as to whether what we recognize as Vitamin D is really a vitamin. It is quite possible that there is an unknown factor in the etiology of rickets not as yet discovered.

VIOSTEROL

By far the most potent specific for rickets is irradiated ergosterol. This drug has been known to have marked antirachitic properties for about six years. Its discovery was made during investigations on cholesterol, which was first thought to contain the antirachitic factor. Investigations in chemical and clinical laboratories led to the recognition of ergosterol as a precursor of the antirachitic vitamin. Ergosterol has been known to be a derivative of ergot and fungi, but nothing was known as to its distribution in the skin and other tissues. When this was recognized it was already known that it could be activated by a small intensity of ultra-violet radiations.

The recommended dosage of irradiated ergosterol has undergone great variations during the few years it has been available for clinical use. This is due to the lack of standardization. The potency of the viosterol now on the market as authorized by the Wisconsin Alumni Research Foundation is 250D. The most comprehensive and practical work on the dosage of viosterol was done by Julius H. Hess[11] and his associates. His observations were made with viosterol 100D except his studies on the effect of massive doses when potencies up to 1000 D were used.

It is difficult to give exact rules for the optimal dose of viosterol 250 D. It may be safely stated, however, that freedom from rickets can be expected if an infant gaining at a normal rate is given from 8 to 10 drops daily, provided the drug is started during the first weeks of life. Premature and rapidly gaining infants must be given larger doses. May[12] suggests that 30 to 60 drops of 100 D (18 to 24 drops of 250 D) is "an effective range for the prevention of rickets in premature infants."

For the care of mild cases of rickets, 15 drops daily should be sufficient. Cases of moderate degree will require 20 drops daily. For the florid cases now rarely seen, larger doses may be required. Results may be obtained if the maximum doses are given only a few times a week. Because of the possibility of toxic symptoms developing it may be well when exceptionally large doses are given to control the medication by occasional estimation of the calcium and inorganic phosphorus of the blood.

ULTRA-VIOLET RADIATIONS

Ultra-violet radiations (290 to 313 millimicrons), a reliable and potent specific for rickets, is associated with the names Huldschinsky[13] and Rollier.[14] The latter was the first to make a definite statement to the effect that sun was the treatment of choice in the cure of rickets. The results are due to a photochemical reaction upon a definite chemical substance. This substance produces among other changes a calcification of the epiphyses easily demonstrated by roentgenograms. The effect on metabolism as demonstrated by Orr,[15] Holt and their colleagues is an increased retention of calcium and phosphorus.

Ultra-violet radiations are obtainable from direct exposure to the sun's rays and from artificial sources such as air-cooled mercury vapor lamps and the arc lamps.

When heliotherapy is the treatment of choice some consideration as to the number of hours of available sunlight is necessary, as well as an estimation of the quality and intensity of the rays. Unfortunately during the winter months, the period when heliotherapy is most needed, the relation between the sun and the earth is such that only a small part of the desirable band of rays is available. The short rays do not reach the earth and the longer ones are diminished in intensity. Moisture (fog), smoke, and dust act as filters. Rays reflected by water or snow and sky shine are valuable. Sky shine has been estimated by Tisdale and Brown[16] as being from one-half to two-thirds as effective as sunshine.

Solar rays when available produce different effects from the more accurately controlled radiations from artificial sources. Clinically this is shown on the skin by ruddier color, an increase of elasticity, an improved texture and a firmer connection with the subcutaneous tissue. The muscles show increased turgor and bony changes (particularly craniotabes) show rapid healing. The roentgenograms are again the most important criteria of progress.

The technic depends upon the month of the year and is wholly empiric not only as to the length of exposure but also as to the amount of skin exposed. It is to be remembered that some of the spontaneous cures of rickets occurring in the spring are in babies who are out of doors a comparatively short time and have only their face and possibly their hands exposed. Our method beginning as early in the spring as the weather will permit is as follows: The legs are exposed for a period of 15 minutes. The following day the legs are again exposed for the same period and then in addition the thighs uncovered for 15 minutes. On the third day this procedure is repeated and an additional 15 minutes of exposure is given to the lower abdomen and buttocks. This method is followed until the entire body has been exposed, unless contra-indications develop. Over-exposure is usually followed by pallor and fever. The skin of infants varies widely as regards the amount of radiations that can be tolerated without producing the very slight flushing that is desirable. It is well known that blondes are far more sensitive to the ultra-violet rays than are brunettes but there are exceptions to this rule. Caution must be exercised at the beginning of the treatment. The mothers should be advised that the tan resulting from ultra-violet rays is not the object of the exposures.

Ultra-violet rays produced artificially are much more easily controlled and much more available in this vicinity than the solar rays. The rays from the carbon arc lamp more nearly approach the solar rays but unfortunately the apparatus has many practical drawbacks. The mercury vapor light gives a ray of shorter wave lengths than the sun.

The treatment here again is empirical and the same caution is to be used as with solar radiation. Our technic is as follows: The exposures are given to the entire body at a distance of 27 inches. The first exposure is for one minute anteriorly and posteriorly. On the third day the exposure is lengthened to two minutes, if there are no contraindications. The exposures are increased one minute every second day until the child is getting seven minutes anteriorly and posteriorly. It is usually possible in this way to give approximately an hour of ultra-violet radiations in two weeks. The usual precautions are taken to prevent injury to the eyes.

The effect is as remarkable and is as easily demonstrated as with the other specifics. Within two weeks new calcification in the epiphyses and carpal centers is demonstrable with the roentgenograms. Clinical improvement is also readily demonstrable.

Hess emphasizes the fact that neither radiations from sun nor from artificial sources produces an indefinite immunity. Attacks of recurrent rickets may develop later in spite of a thorough course of irradiation.

The dosage of the several specifics has been discussed on the premises that each was to be used alone. Such a course is rarely advisable. For example in one case the frequency of upper respiratory tract infections occurring as a complication of the rickets may suggest the use of cod liver oil in order to gain the benefits of Vitamin A but a digestive disturbance may prevent adequate dosage. It may then be advisable to increase the potency of the oil by adding viosterol. Anemia may suggest another combination of specifics, particularly one which includes ultra-violet radiations. Other complications will demand various combinations of the specifics.

Enthusiasm over the results obtained from one tried specific must not permit us to ignore the benefits that can be obtained from other measures. Rarely is it advisable to adhere to one specific in the treatment of any given case. In no instance must our enthusiasm over the treatment of the rickets allow us to overlook the welfare of the patient.

THE RELIEF OF PAIN IN ADVANCED TUBERCULOSIS OF THE LARYNX BY MEANS OF SURGERY*

Martin Nordland, M.D., F.A.C.S.
Minneapolis

THE relief of pain on swallowing is of the utmost importance in the treatment of laryngeal tuberculosis, because as a consequence of pain, there is a diminished intake of food, leading to the rapid failing of the patient. In the past eighteen months, I have had the opportunity of bisecting the internal branch of the superior laryngeal nerve five times, at Glen Lake Sanatorium, for the relief of the dysphagia. The object of this discussion is to call attention to the symptomatic value of resection of the superior laryngeal nerve in far-advanced tuberculosis of the larynx. What the value of this procedure has in the cure of tuberculosis of the larynx must be left for further observation.

CLINICAL APPLICATION

Application of various remedies to the larynx for dysphagia has never been satisfactory. It gives relief for only a short time or sometimes does not help at all and must be repeated too often. This type of treatment would be applicable only where there are small ulcers.

The injection of alcohol into the superior laryngeal nerve, to relieve the pain in tuberculosis of the larynx, as introduced by Hoffmann, has been frequently resorted to. There are many objections to this method. The success of the injections naturally varies with the skill of the operator, and when relief from pain is gained, the duration of the anesthesia fluctuates from a few hours to two months. If it becomes necessary to repeat the injection, it is found that after the first injection all subsequent injections are less likely to be successful, probably because of the development of connective tissue adhesions. Again it has been noted that at times the pain reappears with greater severity after the injection of alcohol. Another disadvantage to the injection of alcohol into the superior laryngeal nerve, worthy of mention, is the possibility of paralysis of the tongue. This is due to the effect of the alcohol extending into the closely related hypoglossal nerve (Fig. 3).

However, the bisection of the internal branch of the superior laryngeal nerve for the dysphagia of tuberculosis of the larynx has many advantages. The surgeon should perform this simple operation when nourishment becomes impossible, on account of dysphagia, because it presents no technical difficulties and is the surest method of removing dysphagia in patients afflicted with laryngeal tuberculosis. The operation has hardly any contraindications.

---

*Presented before the meeting of the Minnesota Academy of Medicine, October 14, 1931.

The internal branch of the superior laryngeal nerve, besides furnishing the sensory fibers to the mucous membrane of the larynx, also furnishes motor branches to the interarytenoid muscles (Fig. 1). This muscle assists in the approximation of the posterior half of the vocal

cords. Therefore, the bisection of the superior laryngeal nerve in the treatment of far-advanced tuberculosis of the larynx has a distinct advantage over other methods, in that it assists in the carrying out of two of the basic principles in the treatment of tuberculosis, namely, that the patient is able to take the proper amount of nourishment, because of the relief from the severe pain of swallowing, and second, because the vocal cords are partially immobilized through the paralysis of the interarytenoid muscles (Fig. 2).

THE ANATOMICAL CONSIDERATION

The object is to expose and bisect the nerve at the most favorable point. For this purpose, it is best to select the course along the hyothyroid membrane. The superior laryngeal nerve arises from the ganglion nodosum of the vagus (Figs. 1 and 3), and, after a short course, divides into two branches, a small external and a large internal branch. The external branch passes downward and mesialward and is finally distributed mainly to the cricothyroid muscle, which tightens the cords. The internal branch passes medially and enters the larynx through the thyrohyoid membrane. It furnishes sensory fibers to the mucous membrane of the larynx as well as motor fibers to the interarytenoid muscle. It occasionally gives off an anastomotic branch to the recurrent laryngeal nerve. The superior laryngeal nerve from its origin lies parallel to and in close proximity with the superior thyroid artery and its branches. The surgical importance of this fact will be referred to later. In the region of the hyothyroid membrane, the nerve is covered by the stratification of the sternohyoid, omohyoid and thyrohyoid muscles.

THE OPERATION

The instruments are the same as those used for the ligature of the superior thyroid artery. The patient is placed in the same position as for thyroidectomy. A few c.c. of 2 per cent solution of novocain are injected subcutaneously at the site for the intended incision. An incision

6 to 7 cm. long parallel to the hyoid bone is made, which extends midway between it and the upper margin of the thyroid cartilage, across the border of the sternomastoid muscle. After dividing the skin, platysma and fascia, the anterior border of the sternomastoid muscle is freed and retracted (Fig. 4). The external jugular vein and great auricular nerve are carefully avoided in the posterior part of the wound. The omohyoid muscle, coming from under the sternomastoid muscle, is then freed along its outer border and drawn inward. If the loop of the superior thyroid artery has not come into view, the large anterior branch between the larynx and the upper pole of the gland serves as a guide. By following this guide, we find the main trunk of the artery lying on the outer surface of the inferior constrictor of the pharynx with the superior laryngeal nerve situated only a little higher up.

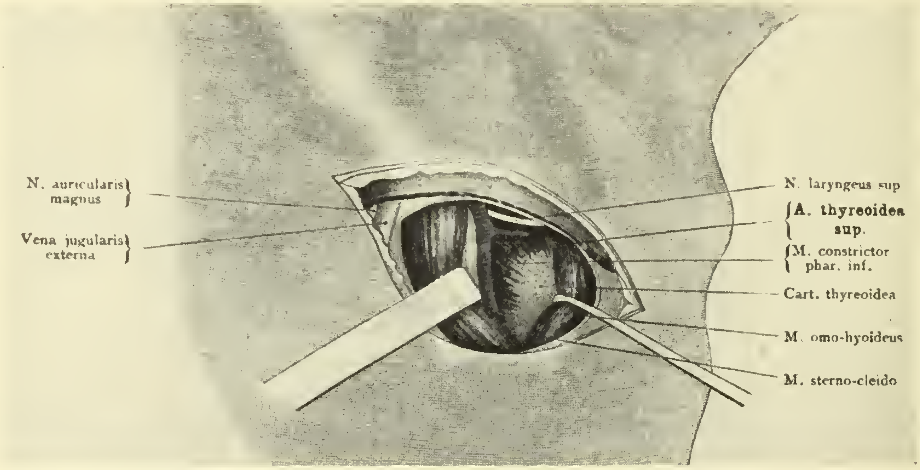

Fig. 4. The incision for the bisection of the internal branch of the superior laryngeal nerve.

Valuable time should not be lost in the application of other methods which will give only temporary relief. Because of the simplicity of the operation and in order to avoid a repetition of the operation on the other side, Wachmann advises that a bilateral operation be made in the first place. Two of our patients had a bilateral operation without the slightest secondary effects. Wachmann, who reported a series of cases in 1916, in which he performed bilateral resection, noticed no trophic disturbances as the result of the resection of both nerves. The wound heals rapidly and does not leave a disfiguring scar (Fig. 5).

After the operation, all painful sensation upon swallowing food disappears immediately. When pain persists after resection of the superior laryngeal nerve, it can be assumed that the ulceration is not confined to the larynx.

In all of our cases, the dysphagia was relieved immediately. In the two cases in which bilateral bisection of the nerve was made, the patients were so much improved after the first procedure that they asked to have the second side operated upon.

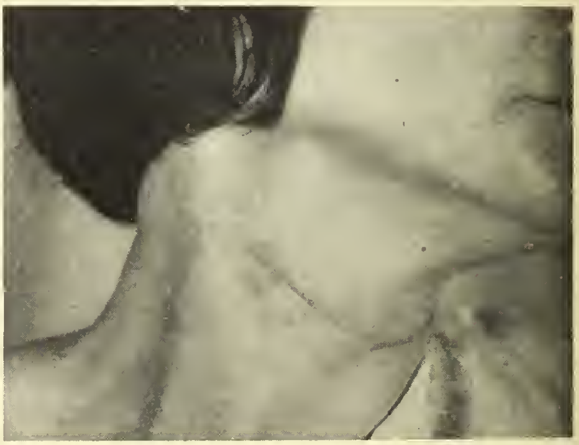

Fig. 5. Case 3. Small scar, four weeks after operation.

CASE REPORTS

Case 1.—Was that of a young man with far-advanced tuberculosis complicated by tuberculous laryngitis. The prognosis was unfavorable.

Larynx.—1. Hoarseness marked commencing January 1, 1930, progressively worse. Throat very sore. Pain on talking and swallowing. 2. Epiglottis destroyed (50 per cent). 3. Left arytenoids three times as large as right, red and inflamed. 4. Pus in posterior half of larynx. 5. True cords thickened, infiltrated and injected.

Operation.—Bisection of right internal branch of superior laryngeal nerve on April 26, 1930.

Result of operation.—Pain on swallowing much relieved. However, appetite very poor on account of general condition and therefore unable to take much nourishment. Also had many stomach symptoms which prevented eating.

Case 2.—Was that of a young woman with far-advanced tuberculosis complicated by tuberculous laryngitis. Hoarseness and occasional soreness of the throat developed early in 1930, soon after the onset of the disease. Within a month, the severe dysphagia became persistent, causing inability to eat.

Larynx.—1. Epiglottis swollen and reddened. 2. Both arytenoids swollen and inflamed. 3. Extensive ulceration right arytenoid extending into posterior commissure. 4. Right true cord pale.

Operation.—Section of right internal branch of superior laryngeal nerve on April 23, 1931. Section of left internal branch of superior laryngeal nerve on July 10, 1931.

Results of operation.—Operation on each side was followed by immediate relief from pain and marked improvement in appetite.

Case 3.—Was that of a young woman with a diagnosis of far-advanced pulmonary tuberculosis complicated by laryngitis. She had burning and soreness in her throat since 1927. Pain became gradually so severe that by May, 1931, she could not eat.

Larynx.—1. Marked bilateral soreness with pain on swallowing. Unable to eat. 2. Epiglottis three times normal size covered with white plaques. 3. Arytenoids markedly enlarged. 4. Small tuberculoma posterior commissure.

Operation.—Section internal branch of right superior laryngeal nerve on July 23, 1931. Section internal branch of left superior laryngeal nerve on August 25, 1931.

Results of operation.—Operation on right side—Immediate marked relief of all symptoms on right side of larynx. No pain on right side. Able to eat much better. Pain on left side of throat. Operation on left side—Immediate marked relief of all symptoms.

CONCLUSIONS

The resection of the superior laryngeal nerve is the surest method of removing dysphagia in patients afflicted with laryngeal tuberculosis.

The operation presents no technical difficulties and does not cause any severe secondary phenomena.

The operation can be done primarily on both sides and is easily borne by the patient.

The operation has a definite symptomatic value and may have a curative possibility.

The operation is suitable for other painful inflammatory processes in the larynx.

THE TESTICULAR HORMONE

Experimental and clinical evidence, as well as numerous studies of transplantations, indicates clearly that the testes possess one or more endocrine functions. In the past the criteria used for determining the effects of the extracts on castrated animals were of doubtful value but more trustworthy methods have been elaborated. While the exact chemical nature of the hormone is not known, some of the chemical properties have been determined. The most active and probably purest preparation thus far obtained is one in which a dose of 0.01 mg. of the active material per capon daily causes distinct comb growth. The product acts best when injected subcutaneously or intramuscularly; the dose for action by mouth is at least ten times as high. Thus far there has been no indication that the product can be of any value in restoring "vigor" to the aged or neurasthenic. However, if there is an indication for its use and if the dosage in man is comparable to that effective in the capon, the daily injection for a man weighing 150 pounds would have to be an amount equivalent to 5 pounds of bull's testis or 2 gallons or normal male urine. If taken by mouth, the dosage presumably would have to be much larger. (Jour. A. M. A., February 27, 1932, p. 738.)

MUCOCELE OF THE APPENDIX WITH REPORT OF A CASE*

Charles Mayo, 2nd, M.D., and John U. Fauster, Jr., M.D.
Rochester, Minnesota

SINCE Virchow, in 1863, first recognized cystic dilatation of the appendix, between 160 and 170 verified cases have been reported in the literature. Virchow considered this condition to be one of colloid degeneration. Rokitansky, in 1867, described four appendiceal cysts which he considered examples of colloid carcinoma, and, in 1877, Ferë first designated this pathologic entity as mucocele. Castle, in 1915, reported from the literature twenty-nine cases in a total of 13,158 records of postmortem examinations. Dodge, in 1916, after an exhaustive review of the literature, found reports of 142 cases. Of these, fifty-five were reported from necropsy, sixty-six from operation, and in twenty-one cases information as to how the study was made was not recorded or was not accessible. Davison, in 1922, added eighteen reports which he had found, together with a report of a case of his own. Since that time there have been reports of cases by Milliken and Poindexter, Weaver, Meyers, Nash, and others.

The following report is a review of the operative cases of mucocele of the appendix seen at The Mayo Clinic from 1917 to 1930, inclusive. During this time out of a total of 31,200 cases in which appendectomy was performed, there were seventy-six pathologically proved cases of mucocele. An attempt has been made to analyze the symptoms, physical findings and associated pathologic characteristics. Six cases, reported by Masson and Hamrick in 1930, were not included in this survey, leaving seventy for consideration.

Thirty-one of the patients were males and thirty-nine, females, and their ages varied from fifteen to sixty-five years, with an average of forty-two and a half years. Analysis of the laboratory work gave very little information. Studies of the blood and urinalysis were made as a routine in all cases. The number of leukocytes varied between 3,800 and 12,100 in each cubic millimeter of blood, with an average count of 7,675 for the entire group. There were no urinary findings of significance in the seventy cases. In eleven cases, analysis of gastric content was made, with variations in the total acids, in terms of cubic centimeters of tenth normal sodium hydroxide, of 70 to 6, and of free hydrochloric acid of 54 to 0.

Twenty-eight of the total number of cases were not associated with any other pathologic condition. All of these twenty-eight patients gave histories of attacks of distress in the right lower abdominal quadrant, varying from a number of years to a few days. In the greater percentage, physical examinations revealed tenderness in this region. In ten of the cases there was an operative diagnosis of acute appendicitis; in five of this number there was preoperative rupture, and in three appendiceal abscess had formed. Two of the patients with abscess had been operated on again within sixty days of the original drainage, and the mucocele was identified at this operation. Forty-two of the total number of patients were operated on for associated pathologic conditions, and, in each case, the symptoms were that of the major condition. Five of these patients gave additional histories of distress in the right lower abdominal quadrant, sufficient to arouse suspicion of recurrent appendicitis. In fourteen of these forty-two cases the condition was associated with cholecystic disease; in twelve, stones were present. There were twelve cases of duodenal ulcer, and two cases of gastric ulcer. One case was identified when the appendix was removed in the course of repair of a postoperative ventral hernia, and another was associated with a perforating carcinoma of the sigmoid.

From this review it would seem that the most significant physical finding, besides the tenderness on pressure in the right lower abdominal quadrant, was a palpable mass in this region. Fourteen patients had a palpable mass in the right lower abdominal quadrant, in seven of which it was proved, at operation, to be due to the mucocele. In the other cases, the mass was due to associated pelvic pathologic conditions. In none of these fourteen cases was a preoperative diagnosis made or suggested. Many cases have been reported in which there was error in diagnosis; the tumefaction in the right lower abdominal quadrant has been mistaken for ovarian cyst, floating kidney, pedunculated uterine fibroid tumor or a malignant condition of the small or large bowel.

---

*From the Section on Surgery, The Mayo Clinic, Rochester, Minnesota. Submitted for publication October 19, 1931.

The majority of those who have studied this condition believe the following to be the facts that are involved in the formation of mucocele: There must be complete, or almost complete, obliteration of the lumen of the appendix. This must be associated with an actively secreting mucous membrane, secreting mucus in excess of absorption, and with some change in the mucosa whereby the normal mucus is changed into pseudomucin. This change should take place in an aseptic field; otherwise, empyema or gangrene would result.

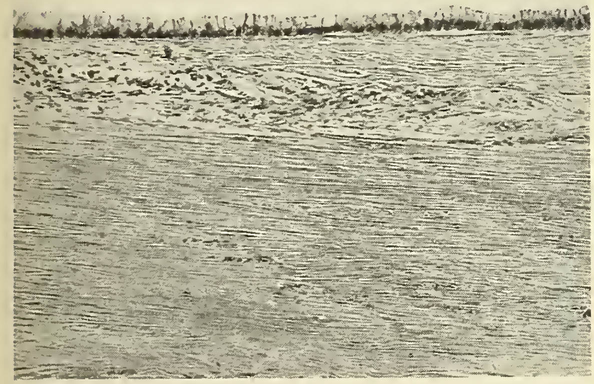

Fig. 1. Section obtained in study of the case reported in this paper. A single layer of tall, columnar epithelium is replacing the normal mucosa.

Microscopically, in the cases we have seen, there has been a change in the height of the mucus-producing cells. Associated with this there is a gradual reduction in number, and the larger the growth, the greater the destruction of the cells. Wellbrock's opinion is that the possibility of this growth being the precursor of colloid carcinoma of the appendix should be considered. Such a growth may be primary, comparable to relatively benign tumors of other parts of the body. That some doubt as to the theory of formation should be entertained is shown by the fact that the number of cases of mucocele of the appendix, in contrast with the number of cases in which the appendixes present obliterated lumens, is very small (Fig. 1).

The most interesting complication of mucocele of the appendix is rupture, with the resulting formation of pseudomyxoma peritonæi. This condition is analogous to that which occurs from ruptured pseudomucinous ovarian cyst, which may be benign or malignant. Masson and Hamrick, following their study of six such cases complicated by rupture, came to the conclusion that the prognosis in pseudomyxoma peritonæi of appendiceal origin is better than in that of ovarian origin; this is due largely to the fact that the exudate, in its escape from the appendix, may be limited to the right iliac fossa.

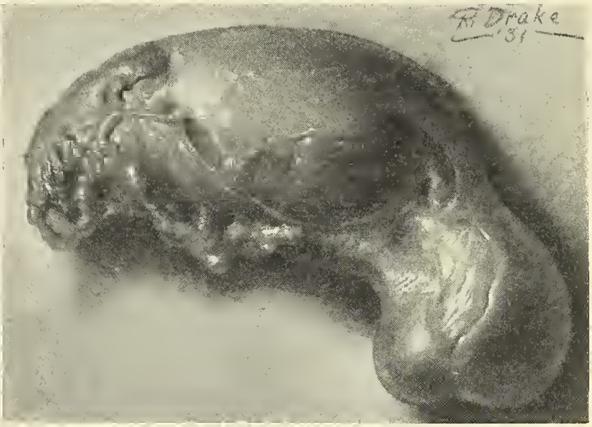

Fig. 2. The mucocele of the appendix in the case reported.

The prognosis in uncomplicated cases is good. There were no deaths in any of our series, and the mortality rate is that of simple appendectomy.

The following is a report of a recent case of mucocele of the appendix in which operation was performed at the clinic.

REPORT OF A CASE

A man, aged sixty-six years, came complaining of failing vision. His general health had always been good except for a tendency to be habitually constipated. For six years previous to his admission he had known of an asymptomatic mass in the right lower abdominal quadrant. Physical examination was negative except for discovery of this mass. A roentgenogram of the colon disclosed an extracecal mass in the angle between the terminal portion of the ileum and the cecum. Urinalysis gave negative results; the concentration of hemoglobin was 12.3 gm. in each 100 c.c. of blood, and leukocytes numbered 5,400 in each cubic millimeter of blood. Operation was advised, and, under spinal anesthesia, a large mucocele of the appendix, resembling in shape a stubby banana, was removed. The specimen was a mucocele, 11 by 4 by 4 cm. (Fig. 2) in various dimensions. In the wall, which was thickened, there was marked fibrosis and hyalinization, with some deposit of calcium. The mucosa was replaced by a single layer of columnar epithelium; the submucosa and muscularis were one continuous mass of fibrous, hyaline tissue containing scattered and collected lymphocytes. The patient's convalescence was uneventful and he was dismissed as cured in fourteen days.

SUMMARY

Seventy cases of mucocele of the appendix are reviewed. In this clinical analysis no definite diagnostic point has been revealed. The most significant facts are the history of distress and palpable mass in the right lower abdominal quadrant. With this present, mucocele of the appendix should always be considered. In uncomplicated cases, the condition is relatively benign. Although mucocele may be a primary type of malignant tumor, its growth is exceedingly slow, and complicating factors are rare. Rupture of larger mucoceles frequently results in the formation of pseudomyxoma peritonæi. The treatment of the uncomplicated case is appendectomy, and the prognosis is good.

SYNTHALIN

No preparations given orally are of proved value in the treatment of diabetes. Synthalin, which has been given the most extensive trial, does seem to be beneficial in an occasional case, but Synthalin is far from being nontoxic and in some patients it produces liver damage. It seems best at present to use insulin and nothing else. (Jour. A. M. A., February 13, 1932, p. 573.)

CASE REPORT

CARCINOMA OF THE LUNG*

William S. Middleton, M.D.
Madison, Wisconsin

A white male laborer, fifty years of age, presented himself to the Wisconsin General Hospital complaining of weakness. His disability began fifteen months previously with a "grippy" attack and at that time he had been told that there was considerable congestion of the right lung. Within a period of two weeks he recovered sufficiently to return to work, a weight loss of 15 pounds having occurred during the period of bedfastness. His strength was not regained, and from time to time he was forced to give up his work. Weakness was the outstanding complaint. Constipation and gaseous distention supervened.

Eleven months after the acute onset of symptoms a new position was obtained with lighter duties occupying him nine hours a day. The fatigue was still so oppressive that he could scarcely walk home in the evening. His appetite failed. After six weeks he became so fatigued that he quit work and stayed in bed for a week. The physician, consulted at the end of this period, determined a fluid accumulation in the right pleural cavity. Three quarts of a reddish tinged fluid were withdrawn and pronounced negative to tuberculosis by laboratory studies. On two subsequent occasions thoracenteses obtained 16 and 6 ounces, respectively, of a clear straw colored fluid.

The inventory by systems established the rapid development of a large nodule on the head over a period of seven months. A febrile reaction ranging to 100° F. had been noted on frequent occasions since the onset. Palpitation occurred occasionally after heavy meals. Dyspnea had progressed over the past five months. A weight loss of 25 pounds had been noted in the past fifteen months.

The past medical history included the usual diseases of childhood. There was an attack of scarlet fever at one year of age, pneumonia at twenty and frequent respiratory infections. A serious laceration to the lateral side of the left knee from a logging hook twenty-five years previously had resulted in a suppurative arthritis with subsequent ankylosis of the knee joint.

The social history was irrelevant, but the family history elicited the occurrence of a neoplasm (probably carcinoma) in the paternal grandmother, tuberculosis in a paternal uncle and a cousin, and insanity in the paternal grandfather and uncle. The contact with the tuberculous relatives had been problematic.

The physical examination developed the following pertinent findings:

Emaciation. A firm nodule, 4 × 6 cm., in the right fronto-parietal region. Perforation in the anterior portion of the bony nasal septum. Diffuse enlargement of the thyroid gland.

---

*From the Department of Medicine, University of Wisconsin Medical School. Presented before the Mississippi Valley Conference, St. Paul, September 21-23, 1931.

Right shoulder lower than left; retraction of the right supra- and infra-clavicular spaces; narrowing of the interspaces on the right; total absence of respiratory excursion at the right apex with gross decrease at the base; tactile fremitus, resonance, breath sounds and voice sounds decreased to absence on the right side except for a small zone above the third rib anteriorly where the breath sounds were almost amphoric and the voice sounds, egophonous; compensatory hyperresonance and exaggerated breath and voice sounds on the left. (The pitch and quality of the percussion note changed from woodeny tympany in the recumbent position to dullness in the upright posture over the second and third right interspaces. No bell tympany, succussion splash nor metallic tinkle were demonstrable over this area; but two days later a typical bell tympany was elicited to the coin test over the third to fifth interspaces on the right.)

Heart displaced to the left.

Left knee fixed in 25° flexion with considerable increase in circumference. Attendant atrophy of left thigh and leg.

In evaluating the physical findings the staff concurred in the opinion of an irregularly pocketed hydropneumothorax; but the history of its course gave much food for thought and discussion. The family history of tuberculosis and the patient's suppurative arthritis were given due attention. The mode of onset was voted suggestive for tuberculosis. Weight loss was an equivocal factor. Had the pleural fluid been serosanguinous on all occasions rather than on a single aspiration, the differentiation would have been simplified. Importantly, cough and sputum had been singularly missing from the picture. Accordingly the laboratory was called upon for assistance.

Important among these findings were the persistent chlorotic type of anemia (4.7 millions erythrocytes with 50 per cent hemoglobin) and the negative sputa. A polymorphonuclear leukocytosis (10,150 to 14,950 with 84 to 93 per cent neutrophiles) pertained. The blood Wassermann reaction was negative. The roentgenogram of the skull revealed a bony defect beneath the site of the visible nodule. The stereoscopic roentgenograms of the chest (Fig. 1) showed the following details: Trachea was visualized in the midline. The right vertebral, first and second interspace distributions showed some fibrous thickening and there was a granular increase in density in the left first interspace. The radiolucency on the right was greatly decreased and a cascading series of horizontal fluid levels with elliptical zones of rarefaction above each was observed at various levels in the right thorax. The opacity of the right lung field obscured the right border of the heart, the mediastinum and the diaphragm.

While the persistently negative sputa argued against diagnosis of pulmonary tuberculosis, the first directional support for a neoplasm of the lung came in the roentgenologic evidence of a bony defect beneath the parietal nodule, which continued to increase in size after the patient's entrance to the hospital. Not until the twentieth day after admission did the opportunity for a biopsy present itself in a small firm nodule in the right pectoral chain of lymphatics. (The surgeons had advised against section of the cranial nodule.) The sections of this node were diagnosed carcinoma.

The clinical course during the period of hospitalization was marked by steady weight loss, recurrent accumulations of serous and later sero-sanguinous fluid in the right pleural cavity, afternoon fever ranging from 99.4 to 101.2° F. and extreme dyspnea. Very late in the course of the disease there were several small hemoptyses. The patient died on the fifty-third day after entrance.

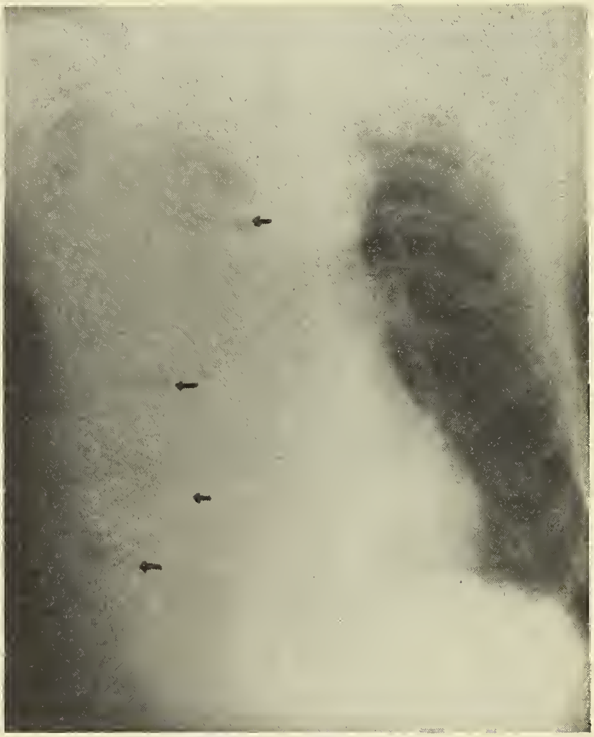

Fig. 1. Roentgenogram of chest. Arrows indicate several fluid levels.

The postmortem examination as reported by Dr. Gorton Ritchie was especially interesting in the details related to the primary neoplasm and its metastases. The right lung was found to be totally collapsed with a dense pleural covering, cartilaginous in consistency. The lung substance was atelectatic, doughy, greyish green in color with numerous strands of white tissue, cartilaginous to the knife, extending throughout the same. These white trabeculæ were especially prominent at the lines of the interlobar septa. The bronchi were considerably stenosed and the tracheo-bronchial nodes were involved in a mass of this cartilage-like tissue. At the base of the right lung was a large mass of firm, elastic tissue involving the whole right leaf of the diaphragm. This tumor was densely adherent to the body wall in all directions and the diaphragm beneath was 1.5 cm. thick.

The liver contained numerous umbilicated light colored nodules; and on section the exposed surfaces of all portions of the organ were studded with many firm white nodules. These were contrasted with the congestion of the remainder of the surface.

The histological study of the tumor and metastases in the liver and bronchial lymph nodes showed an alveolar type of atypical epithelial growth in the main (Fig. 2). There was a small amount of connective tissue stroma in the same. Many tumor cells showed vacuolation and degenerative changes in the nuclei. In places there appeared a dense overgrowth of fibrous connective tissue. There was some bone formation. Very importantly some portions appeared to have been derived from bronchial epithelium.

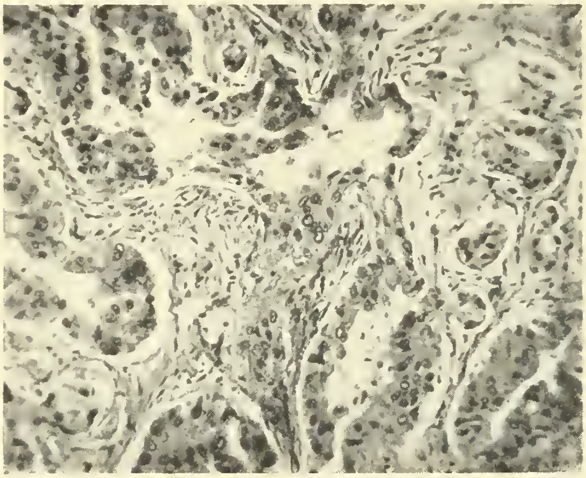

Fig. 2. Photomicrograph of histologic section of carcinoma. Courtesy Dr. Gorton Ritchie.

This patient well illustrates many of the difficulties presented in arriving at a differential diagnosis between primary carcinoma and tuberculosis of the lung. Pleurisy with effusion, weakness, weight loss, afternoon fever and chest signs, particularly in a patient with a history suggestive of exposure to tuberculosis and a definite antecedent suppurative arthritis might well arouse the suspicion of a tuberculous background. The occurrence of a serosanguinous effusion favored neoplasm. The absence of a cough, persistently negative sputa and conspicuous dyspnea also pointed toward this conclusion. It remained for the laboratory to suggest the diagnosis in the lead afforded by the cranial defect and to clinch the same in biopsy findings on the lymph node from the pectoral chain. Interestingly, histologic studies of materials obtained at necropsy indicated that the carcinoma of the lung was of the rarest type, alveolar-celled. Carcinomata from the bronchial mucous glands and from the bronchial epithelium are more common. Objection was raised at the time of the biopsy report to the suggestion of a bronchial origin. As a rule such cases have persistent cough and blood streaking of the scanty sputum as relatively early symptoms, whereas in this case cough was never a volunteered symptom and small hemoptyses occurred very late in the course. It is difficult to account for the absence of pain in this case unless it resulted from the stoicism of the patient.

The symptoms of carcinoma of the lung vary widely with the nature of the lesion, its location and direction of extension, encroachment upon the lumina of bronchi or surrounding structures, pleural involvement and metastastic routes. In the present relation, time is not afforded to discuss this matter in any detail. Whenever the question of the differentiation between primary carcinoma and tuberculosis of the lung arises, the clinician must bear in mind the frequency with which cardinal symptoms of tuberculosis, persistent cough, hemoptysis, fever, pain, dyspnea and weight loss are seen in carcinoma of the lung. In qualification it should be stated that the pain of neoplastic infiltration is rarely pleuritic. It may be sharp or dull, but rarely does it have the same relation to respiration as does pain in tuberculosis. Dyspnea is far more common and distressing in carcinoma than in tuberculosis. The question of fever in carcinoma of the lung is an interesting one. Professor Riesman has for many years taught that not only is carcinoma of the lung the tumor most frequently attended by fever but also that fever should suggest rather than refute such a diagnosis. In the experience at the Wisconsin General Hospital necrosis is a more common explanation for this febrile reaction than infection.

The physical findings of primary carcinoma of the lung may be negligible or absent for a considerable period of time. If present, several factors modify them, namely accessibility, bronchial encroachment and pleural involvement (with or without effusion). Since the bronchogenic type of carcinoma (mucous glandular and epithelial) occurs much more frequently than the alveolar form, particular attention should be paid to alterations in the aeration and vibratory phenomena of the several lobes of the lungs of patients in whom the suspicion of pulmonary tuberculosis can not be confirmed by ordinary laboratory measures.

In the hands of qualified experts bronchoscopy offers the greatest promise of success in the diagnosis of carcinoma of the lung, especially of the bronchogenic order. The direct visualization of the lesion is possibly less useful and certainly less convincing to the general practitioner than the biopsy materials so obtained. The roentgenogram is helpful in a certain proportion of cases. In the general hospital this aid is not as widely applicable as one might judge theoretically. The wedge or triangular shaped infiltration, base to hilum and apex to periphery, should suggest this lesion in the majority of instances of bronchogenic carcinoma seen before wide extension or pleural involvement has masked the picture. The unilateral solitary nodule or mass in the lung field may by progress studies be definitely defined as a neoplasm, but abscess, gumma, infarct and other conditions must enter into the consideration for differentiation. The metastases to accessible lymph nodes frequently afford a fortunate diagnostic aid to the hard-put clinician. Not uncommonly these metastases in the immediate supraclavicular, axillary and pectoral nodes are very small and inconspicuous. Where the thought of a primary carcinoma of the lung is entertained, particular search should be made for these invaluable guides.

In so far as the diagnostic results are concerned, the experience at the Wisconsin General Hospital is probably a fair criterion for similar institutions in this direction. Over a period of six years the diagnosis of primary carcinoma of the lung has been made twelve times. In this group eight were males and four females. Eight were of bronchogenic origin and two, alveolar-celled. The histologic returns are not available on the remaining two. Necropsies were performed upon eight of the series, and in two of this group the diagnosis was thus made for the first time. In one of these individuals a clinical diagnosis of tertiary syphilis had been made, while in the second the bilateral distribution of the primary carcinoma of the lung had proved misleading.

In analyzing the aids to the correct diagnosis in ten of twelve cases at the Wisconsin General Hospital, the clinical course and the physical findings were helpful in a majority. Biopsy of accessible nodes concluded the diagnosis after suspicion had been aroused in six of the ten positive antemortem diagnoses. A diagnosis by bronchoscopy was afforded in only one instance. Roentgenologic study gave the first clue in three subjects. Accordingly it may be concluded that no single factor in the diagnosis of primary carcinoma of the lung may be stressed to the exclusion of others. Only by attention to the details of the history and clinical course supported by every available measure of physical and laboratory diagnosis may a fair percentage of these cases be diagnosed antemortem. Considerable stress has been placed upon the utility of biopsy studies of accessible lymph nodes in clinching the diagnosis. Of course such implants represent metastases and in so far as therapy is concerned, a stage beyond recall of present measures of treatment. If eradication is to be effected, earlier diagnoses must be made; and the roentgenogram and bronchoscopic study offer the greatest promise in this direction.

OVERSUPPLY OF TRAINED NURSES

Training schools must curtail the steady production of more nurses or the morale of the nursing profession will break down completely. This is the opinion of the Committee on the Grading of Nursing Schools, following an analysis of early returns of the 1930 census on workers.

How serious the oversupply of graduate nurses has become is revealed by the Grading Committee after tabulating figures for eighteen states and the District of Columbia. For this group, since the 1929 census, the total population has increased 7 per cent, while the total number of trained nurses has increased 78 per cent.

Although there are still areas of the country and groups of patients not properly nursed, owing to poor distribution and lack of special training, the figures for the forty-two cities studied show that the average nurse has no more than 149 days of employment in any given year, according to the present sickness rate. In Bangor, Maine, she has not more than 77 days of work, and in Ottumwa, Iowa, where employment conditions are best among the cities studied, she can work not more than 201 days in the year. Rates for the other cities range between these two.

States as a whole are somewhat less oversupplied with nurses, although in New Hampshire the nurse can expect no more than 190 days of work in the year, and in Maine, Vermont, Iowa, North Dakota, South Dakota, Kansas, Delaware, Montana, Wyoming, Arizona, Nevada, Idaho and the District of Columbia there is not nearly enough nursing to be divided between the trained and untrained nurses competing for patients.

Untrained nurses are not on the increase, census figures show, but trained nurses are being turned out to terrific competition by the thousands each year. In Maine, for example, there was in 1900 one trained nurse for every 5,068 persons; in 1910, there was one for every 910; in 1920, one for every 579, and in 1930, one for every 349.

"If nursing is to avoid disaster," says Dr. May Ayres Burgess in presenting these figures in the March number of the *American Journal of Nursing,* "the steady production of more students, who become graduates, must cease. It must cease not only in the small schools, but in most of the large schools as well. Graduate nurses must be employed. If they are unemployable, they must be reëducated. The schools of nursing have produced them. They are members of the profession. Unless their morale is to break down completely, they must either be eliminated or utilized.

"This is a year of national economic distress. Hospitals are short of funds. How, then, can hospitals take care of their patients with reduced numbers of student nurses, with increased numbers of graduate nurses, and without increasing the annual budget? Let us not assume that there is no solution for this problem. Nurses who are intimately familiar with hospital administration may be able to discover new economies, new methods of organization, which will make reductions in the number of student nurses possible. Unless some solution can be found, which it is within the practical means of the hospital to adopt, nursing will continue to grow in numbers and in distress."—American Nurses Association.

A FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

Help the Veteran

When the World War Veteran first came home from the wars, the army itself was looking after his affairs. Also the United States Public Health Service, if he was disabled, and the Red Cross.

Before long, however, the army and the health service dropped out of the official picture and a brand new government bureau to be known as the Veterans' Bureau took their place. This bureau was to have charge of hospitalization of veterans still suffering from war disabilities. It was to rate them for purposes of disability compensation, to straighten out war risk insurance tangles and generally to administer, in the interest of the veterans, the growing volume of veterans' law. In the meantime the service men's organizations were growing up, the American Legion, the Disabled Veterans of the World War, the Veterans of Foreign Wars, all of whom established agencies to help the veteran to get his rights under the law. The Red Cross also went right on acting as a friendly intermediary for the ex-soldier.

In 1923, it was brought to the attention of the legislature of the state of Minnesota that in spite of all this organized overlapping system of veterans' aid, the veteran still needed help. Thus the Division of Soldier Welfare was established under the wing of the State Board of Control with a large enough yearly appropriation to set up an office and employ several persons, 80 per cent of whose time has been taken up in the past nine years in helping the veterans to get a fair hearing on compensation claims or to get needed hospitalization from the Veterans' Bureau.

All this in spite of the fact that it was the obvious intention of Congress in setting up the Veterans' Bureau that the bureau should give all necessary aid in securing the rights of ex-soldiers.

It is a foolhardy veteran, now, who submits any sort of claim to the bureau even for simple, routine hospitalization, who does not enlist the liaison officer of his service organization, or the Division of Soldier Welfare, or the Red Cross, or a Congressman, or all four, to help him.

It should not be said, either, that the situation is the fault of the many hard-working, wholly well-intentioned officials of the Veterans' Administration, itself.

But insofar as it affects needed hospitalization and medical care for men who are entitled to such care, it is a situation of real interest to physicians. One important consideration back of the confusion, attendant upon getting a man into a veterans' hospital, is lack of beds. In spite of millions already spent and millions more authorized for the purpose of building more government hospitals, there are not now and probably never will be enough beds in government hospitals.

The solution to the whole situation—and to the elimination of a great deal of wasted money and time—lies in the use of standard civilian hospitals near the home of the veteran for the acute illness and the emergency case. There are plenty of beds in good civilian hospitals where first class medical care is immediately avaialble. In fact these same civilian hospitals are facing a serious administrative and economic problem because of their heavy percentage of empty beds. No waiting and wire pulling ought to be necessary to secure for the acutely sick veteran the use of them.

Ramsey Prepares Its Resolution

Seven sub-committees of the Ramsey County Medical Veterans will undertake a thorough study of the veterans' hospitalization situation upon which a suitable resolution on the subject, for presentation to the American Legion, may be based.

Each committee will investigate one phase of the problem to be dealt with in the proposed resolution. It is obviously necessary to appeal to the veterans themselves, through their service organizations, on any proposal to improve this admittedly difficult situation. The Ramsey county organization is wisely getting its facts before it makes any proposal which is to stand the scrutiny of the officials of its local Legion Posts.

Vol. XV APRIL, 1932 No. 4

THE STATE MEETING

Final arrangements are now under way for what is undoubtedly to be the most varied and colorful and universally interesting annual meeting of the Minnesota State Medical Association. This meeting is scheduled for May 23, 24, and 25 at the St. Paul Auditorium.

An entirely new program scheme by which no less than three important program sections and sometimes as many as fifteen or twenty sections will be held simultaneously, took shape at the third meeting of the 1932 Committee on Scientific Assembly held at the St. Paul Athletic Club Saturday, March 12.

The unusual interest displayed in advance by the membership of the Association was cited by members of the Committee as necessitating this year's enlarged program. It is to include separate medical and surgical sections; some forty small group table demonstrations; programmed motion pictures on a variety of subjects; and an afternoon of clinics. Program requests coming, more than ever before, from members outside the four large medical centers have chiefly dictated the structure of the program, which will be of especial use and appeal to the general practitioner. As a result, also, many more men than usual from the rural districts will read papers before the various sections of the program.

The total number of men appearing on all of the programs will exceed 120, the committee announced. Among these, besides a representative group of distinguished Minnesota physicians, are several interesting out-of-state speakers. Dr. Walter Sebening of Frankfort-on-the-Main, Germany, who has spent six months in America studying American surgical management of peptic ulcer, will appear on the surgical section of the program. Dr. W. C. Campbell, orthopedic surgeon of Memphis, Tenn., will address one of the noon general sections, as well as Dr. Theodore N. Davis of Greenville, S. C., and Dr. Ralph Major of Kansas City.

The scientific sessions begin with two conferences, one clinico-pathological and the other radiological, on Monday afternoon. They will deal principally with pulmonary tuberculosis and nontuberculous pulmonary disease.

The medical economics meeting is scheduled to unite the medical association and the Minnesota State Hospital Association, which is also convening at the Auditorium on the same date, in one large general meeting to be held in the Auditorium theater. The subject for discussion at this meeting will be "Medical and Hospital Care of Veterans," and a group of representative physicians, hospital men and laymen will talk on the various phases of the subject. Among the Monday night speakers already scheduled are Father Maurice Griffin of Cleveland, Ohio, Board of Trustees of the American Catholic Hospital Association; Dr. Olin West of Chicago, secretary of the American Medical Association; Mr. Frederic R. Bigelow of St. Paul, and Mr. E. V. Cliff of Ortonville, Executive Committee of the American Legion.

The Tuesday scientific program opens at 8 A. M. with simultaneous medical and surgical sessions, the surgical session occupying itself for a considerable part of the time with surgical aspects of obstetrics, and the medical section chiefly with cardiac disease, cardiac neurosis and a general consideration of the rôle played by quackery in the management of neuroses.

At 10 A. M. the entire membership will adjourn to the exhibit hall for the small group table demonstrations which are to occupy an entire hour on both Tuesday and Wednesday mornings. The subjects already definitely determined upon for these demonstrations include eyegrounds; ulcerative colitis; the physiological action of animal venom; the use of the artificial larynx; peripheral vascular disease; the photoelectrometer as applied to hemoglobin demonstration; the Friedman hormone test; Congo red test for amyloids; syphilis, practical points and therapy; trichomonas vaginalis; the tuberculin test; tularemia; varicose leg ulcers; typing for pneumococci; horseshoe kidney; lung abscess and lipiodol; foreign bodies and medical conditions in the esophagus; blood transfusion; undulant fever; primary tuberculosis in childhood (X-ray films); fresh pathology; cauterization of the cervix; audiometer; Schick test; blood; cholecystographic technic; surgical treatment by maggots.

A joint session of all sections will follow at 11 A. M on Monday, addressed by Dr. Campbell, on the subject of Fractures in and about the Neck of the Femur. Another joint session following lunch will be on the general subject of malignancy, with Dr. W. J. Mayo presiding. The medical section for the afternoon opening at 2:30 will include, among other varied subjects, a symposium on diseases of childhood. The surgical section for the afternoon will devote itself to different surgical problems involved in thyroid disease; intussusception in infants; tuberculosis of the kidney; cancer of the rectum.

The big social event of Tuesday night will be the annual banquet of the association to be held at the Lowry Hotel. Speakers for the affair will be Dean R. E. Scammon of the College of Medicine of the University of Minnesota, who will talk on "The Relation of the Medical School to the Man in Practice"; Rev. W. C. Sainsbury of Fargo, North Dakota, whose subject will be "The Family Doctor"; and Dr. M. S. Henderson of Rochester, president of the State Association.

Wednesday's scientific sessions will follow the Tuesday schedule with separate medical and surgical sections meeting until 10 A. M., followed by the table demonstration hour and the joint session terminating at 12.

A joint session of an hour will open the final Wednesday afternoon session followed by two and one-half hours of clinics, to be held also at the Auditorium meeting place.

The paper on peptic ulcer by Dr. Sebening to be read in the course of the morning surgical session will be a high light of the day, with two other headliners figuring at the joint sessions of the morning and afternoon programs. The latter will be the explanation by Dr. Davis of South Carolina of his method of prostate resection and also the discussion of hypertension by Dr. Ralph Major of Kansas City in the afternoon.

A special clinic in first aid has been arranged for Minnesota Highway Patrolmen for Wednesday afternoon, preceding the afternoon clinics, which are to include dermatology, neurology, cardiac, fracture, pediatric, and surgical clinics.

The separate medical section will devote itself to a variety of subjects, including recent developments in endocrinology; treatment of chronic arthritis with intravenous vaccines; and evaluation of the periodic medical examination.

A special program feature is to be made of the moving picture theater to be set up in the exhibit hall. A series of eleven films, some of them talking films, have already been secured. These will be shown at definite programmed times, the committee announces, and the program will be continuous. Among the films already booked are "Cancer of the Skin"; "Bone Tumors"; "Puerperal Infection," produced for Dr. D. H. Bessesen; "Preliminary Hemostasis in Goiter Surgery," produced for Dr. Martin Nordland; "The Tucking Operation for Strabismus," produced for Dr. Frank E. Burch; "Delivery of Twins," produced for Dr. J. J. Swendson; "The Gillette State Hospital for Crippled Children"; "Features in Hospital Administration"; "Repair of Urethrocele, Cystocele, and Lacerations of the Cervix"; "Repair of Second and Third Degree Lacerations of the Perineum and Rectocele." The committee announces that there will be time for a few more films besides these and invites association members to submit any others they may have for this showing.

An unusually large number of scientific and technical exhibitors have already taken space in the large ground floor exhibit hall in the fourth street ball room. Among them are the yearly increasing number of individual exhibitors competing for the gold medal annually offered for the best exhibit by an individual Minnesota physician by the Southern Minnesota Medical Association.

The tentative schedule for the business meetings provides for dinner meetings of the Council and the Reference Committees Sunday night, May 22, preceding the official opening of sessions. At 9 A. M. Monday the first meeting of the House of Delegates is scheduled, to be followed by a 12 o'clock luncheon meeting for this body on Tuesday, May 24. The Council is to meet again Monday noon, May 23, and at 2:30 P. M. Tuesday afternoon. Presentation of new officers will take place Wednesday morning, May 25.

Minnesota Alumni luncheon and fraternity luncheons are scheduled for Monday, Tuesday, and Wednesday noons. Arrangements for other social events, including the annual golf tournament, are pending.

The program of the Women's Auxiliary, which is holding its annual meeting, as usual, at the same time as the medical association, will concentrate this year on a series of round table discussions. These discussions, all relating to problems of public relations, will be led by Dr. O. E. Locken of Crookston, Dr. C. B. Wright of Minneapolis, and others. The annual Board meeting of the organization will be held Tuesday morning. Dr. Walter Alvarez of Rochester will be guest speaker at the annual Auxiliary luncheon, Wednesday, May 25. Dr. Alvarez' subject will be "Foods."

TRANSURETHRAL RESECTION

Of the various infirmities which beset the aging man, none is more distressing than that of prostatic obstruction. It has been said that one man in three will be afflicted with enlargement of the prostate gland. Fortunately, however, such enlargement will actually obstruct the urinary bladder in only a relatively small number of cases. Obstruction is dependent not so much on the size of the gland as the position the hypertrophied gland assumes in relation to the neck of the bladder. Thus only a relatively small portion of the gland may protrude into the outlet of the bladder or impinge on it so as to cause difficulty of urination. Secondary inflammation of the tissues surrounding the internal sphincter and prostatic portion of the urethra, followed by contraction at the neck of the bladder, is also a frequent factor in causing obstruction.

To give surgical relief for prostatic obstruction has always been a formidable procedure. A generation ago it was accompanied by a frightful rate of mortality, so that many of the victims preferred to suffer palliative catheterization or suprapubic drainage rather than take the risk of prostatectomy and its complications. With improvement in surgical methods, and particularly in preoperative and postoperative care, the rate of mortality has in recent years been greatly reduced. In spite of every precaution, however, prostatectomy is occasionally followed by complications such as persistent infection of the urinary tract, stricture of the prostatic portion of the urethra, incontinence, persistent suprapubic or perineal fistula, and rarely by re-formation of prostatic tissue. The economic factor is also a formidable feature of prostatectomy, since it requires hospitalization with both medical and nursing care over a period averaging eight or ten weeks. It is obvious, therefore, that any method which gave the slightest opportunity to circumvent so formidable a procedure would be seized by the physician and layman alike. It is only natural, then, that in recent months a procedure termed transurethral prostatic resection should have aroused widespread interest.

It has been the history of many therapeutic procedures that one step leads to another until a method is evolved which is widely applicable. Removal of obstructing portions of the prostate gland through the urethra has had such a career. Such removal began with the early, unsatisfactory attempts of Mercier and Bottinio. Later, this procedure was revived with the employment of the endoscopic approach by Goldschmidt, Young and Luys; then it was further developed, and its field was amplified by Caulk, and recently it was refined and broadcast through application of visualization by Stern, Davis, McCarthy and Bumpus. The method formerly called "the prostatic punch operation" has been more recently dignified by the urologist, so that it now bears the somewhat imposing term of "transurethral resection." In the hands of an experienced and skillful urologist, transurethral endoscopic resection undoubtedlv will prove to be an invaluable addition to methods of treating prostatic obstruction. Its many advantages, such as lowered mortality, comparative freedom from permanent complications, reduction in duration of hospitalization, and reduction in time of postoperative care and convalescence, are obvious. Its superiority in removing commissural obstruction resulting from contracture of the vesical neck, or that caused by enlargement of the median lobe of the prostate gland, is undoubted. Minor degrees of enlargement of the lateral lobes also should be regarded as amenable to such resection. There is much evidence, however, which tends to support the conservative surgeon in his contention that, with marked enlargement of the lateral and median lobes, the best permanent results can be obtained by prostatectomy. On the other hand, even in this group of cases, excellent results have been claimed by the enthusiastic endoscopist, so that time alone will have to decide. The chief argument against transurethral resection, with obstruction of lateral lobes, is the probability of recurring obstruction because of incomplete removal. The average interval of time before obstruction recurs has not as yet been determined in a large series of cases. Even so, repetition of transurethral resection is not a formidable procedure, and if the patient is free from urinary symptoms during an interval of several years, he would probably be willing to take the chance.

It is of considerable interest that the old-fashioned case, in which there is a huge, hypertrophied prostate gland, with distended bladder, is now seldom observed. Instead, the patient of today who seeks medical advice soon after onset of symptoms, usually has only 30 to 60 c.c. of residual urine, and on rectal examination the prostate gland is found to be only moderately enlarged. This earlier consultation is undoubtedly the direct result of numerous communications, written by members of the medical profession, which have appeared in both medical and lay journals in the last decade. In the majority of these cases, the condition is amenable to transurethral resection.

Transurethral resection has come to stay. Whether its field will be expanded to include every case of benign prostatic obstruction remains to be seen. It is obvious that the best results from endoscopic resection will be obtained only with skill and wide experience.

W. F. Braasch, M.D.

OCCUPATIONAL THERAPY IN MINNESOTA

A realization of the value of occupational therapy for those temporarily or permanently disabled by accident or disease was one of the few tangible good results of the World War. Interest in this form of reconstructive work has persisted to some extent during the post-war period in its application to every-day casualties, but the medical profession is not acquainted with the nature or extent of this activity in our own state.

Occupational therapy consists of work specially selected for the patient partially or totally incapacitated by accident or disease, to accelerate the individual's return to his vocation or when necessary the teaching of new trades. The various centers are not self-supporting, as the money realized on the sale of articles less the cost of materials is turned over to the worker. Thus the various therapeutic centers require some financial backing.

The economic value of this type of work is considerable. It hastens the return to economic independence and thus relieves the always heavy burden on charitable undertakings. The psychic effect on the patient is fully as important. These individuals are given work, which is an essential to happiness, and are able to be at least partially self-supporting. Their morale as well as that of the institution is thus enhanced. Patients as a rule are enrolled only on recommendation of the attending physician and the type of work is selected in coöperation with a trained supervisor. Physiotherapy is a valuable adjunct in many instances and should be available at each center.

The training is carried out, in the larger centers of population, at headquarters known as curative work shops, in the hospitals, and in the home. Games and entertainment in the form of reading are adjuncts in the hospitals particularly.

The type of cases enrolled includes those suffering from fractures, encephalitis, spastic paralysis, poliomyelitis, nerve injuries, congenital deformities, arthritis, heart disease, tuberculosis and mental trouble.

In the larger centers of population—Minneapolis, St. Paul, Duluth, St. Cloud, and Rochester, for instance—vocational centers have been in operation for a varying number of years. These are supported by different agencies.

In Minneapolis the Curative Work Shop is being supported by the Citizens Aid Society and the Minneapolis Foundation as a demonstration of the need for such a service. The shop is under the direction of the Visiting Nurse Association but is a project of the Junior Board of the Visiting Nurses Association and the Junior League of Minneapolis.

In St. Paul, a Curative Work Shop was established in 1928 as a private enterprise by its director, Miss Martha R. Eming, as a demonstration of its need. Over a hundred cripples have been enrolled. Efforts so far to interest charity organizations or those philanthropically inclined have been unavailing and financial assistance will be necessary if the work is to continue.

In Duluth an organization known as the Duluth Association for Physically Handicapped sponsors the work, which is carried on in St. Mary's and St. Luke's hospitals and among the home-bound.

Many of the state institutions for the insane and the county tuberculosis sanitaria have their units.

Occupational therapy is taught at schools, sanctioned by the American Medical Association, at Boston, Philadelphia, St. Louis, Northwestern University, and Milwaukee Downer College. Graduates are registered in the American Occupational Therapy Association, of which the Minnesota Association of Occupational Therapy is a component organization. The state branch holds quarterly meetings in different parts of the state for the purpose of promoting the work and keeping up professional standards.

We know of no more worthy constructive undertaking than this. The insurance companies might well become interested from the money standpoint. Each community should possess a center and furnish the necessary financial support. The physician is in a position to lend his coöperation.

VEGE-SEA AND ORO BRAND KELP SALT NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that "Vege-Sea" is stated by the Oakland Food Products Co., Oakland, Calif., to be dried and powdered kelp, while "Oro Brand Kelp Salt" is stated to be a flavored mixture of this kelp with ordinary salt. The marketing of dried kelp or of a mixture of kelp and salt does not present any originality, and hence there is no warrant for the sale of these preparations under coined names. The Council found "Vege-Sea" and "Oro Brand Kelp Salt" unacceptable for New and Non-official Remedies because they are marketed with claims that are unwarranted and misleading and because the recognition of proprietary names for these unoriginal preparations is not in the interest of rational therapy. (Jour. A. M. A., February 20, 1932, p. 640.)

MISCELLANEOUS

MOST GOVERNMENTS ARE INEFFICIENT OR CORRUPT—SOME ARE BOTH (Continued)*

Edward H. Ochsner, M.D.
Chicago, Illinois

The founders of our government subdivided it into three branches: the administrative, the legislative, and the judiciary. This was done on the theory that each had a distinct function to perform and that they would all act somewhat as checks and balances upon each other. This seemed logical at the time and undoubtedly has many advantages, but our founders did not and could not foresee one of its dangers and one of the abuses to which this division was to be put, namely, the practice of sidestepping duty and responsibility. One of the chief governmental in-and-outdoor sports today is "passing the buck," with an "open season" the year round.

In a project involving as many problems as Social Insurance does, all the branches of the government would be involved in its execution—the administrative in administering it, the legislative in enacting the necessary laws, and the judiciary in adjudicating them. Let us then examine briefly how the different branches have deported themselves in the more recent past. Let us start by examining just one typical administrative activity of both the federal and the state governments.

Individual members of the medical profession have repeatedly called attention to the great need of a careful study of all delinquents and criminals in our state and federal institutions in order to determine the mental and physical condition of each member of these two classes with a view to their rehabilitation and possible reclamation, and yet almost nothing has been accomplished along these lines by governmental agencies. Dr. Frank L. Rector who recently completed a survey under the auspices of the National Society for Penal Information on health and medical work in all state and federal prisons and adult reformatories, states unequivocally that in not one of these institutions is there a well-rounded balanced medical and health program. While some of them provide acceptable accommodation for the care of the acutely sick or injured, there is little or no provision for the rehabilitation of the physically handicapped so that they will be better equipped for earning an honest living after their discharge to civilian life.

Just one typical example. On the day Dr. Rector visited the Ohio State Penitentiary, there were four thousand four hundred seventy-five prisoners within its walls, of which one hundred fifty-six were hospitalized. There was but one physician on the staff, all other attendants at the hospital being prisoners. While the physician was nominally on a full time basis he was carrying on an outside private practice as his salary from the state was insufficient to meet his living expenses. What can one part-time physicians accomplish with that many patients, a large percentage of whom are physically handicapped, mentally abnormal and emotionally maladjusted? Ohio is a fair example. In most of the other penitentiaries and in the federal prisons, conditions are no better and in some even worse.

Now let us investigate some of the legislative problems. While nearly every legislative body contains some men of outstanding ability, the great majority of legislators have not the slightest conception of what is required of their position and blindly follow their party bosses, who are not generally known for their altruism, their patriotism, or a burning desire to promote the public welfare. One of the worst features of our legislative activities is the fact that a small, well-organized and insistent minority can usually get its measures enacted into law unless some other group is adversely affected by the proposed legislation and makes a counter-attack.

Another bad method of securing legislation is the system of trading. An interesting occurrence of this sort happened in the state of Illinois in 1923. About that time a Chicago mayor was disgracing not only his city and state but the nation by the slogan, "Hit King George on the Snoot." A free citizen from the corn lands of the state decided that he would like to be sent to the state legislature, took up the battle cry, had just one plank in his platform, namely to make the American language the official language of the state. He was elected. By use of extensive vote trading he secured the passage of the following:

OFFICIAL STATE LANGUAGE

An act establishing the American language as the official language of the State of Illinois (Approved June 19, 1923. L. 1923, p. 7). Preamble.

177 (American language). 1. Be it enacted by the people of the State of Illinois, represented in the General Assembly:

The official language of the State of Illinois shall be known hereafter as the "American" language.

So much for administrative and legislative inefficiency. The next article will take up the judiciary.

---

[*] One of a series of articles appearing in state medical journals on various phases of socialized medicine.

AN UNUSUAL URINARY PARASITE OR CONTAMINATION

John M. Culligan, M.D., M.S., F.A.C.S., and
Bernice Medley
Saint Paul

During a routine urinalysis of a patient, organisms were seen which we had never observed before. The patient was a male, single, seventeen years of age, who consulted us for a condition which was related in no way to the urinary system, and he had no complaints referable to the genito-urinary tract.

The organisms were living. Their bodies were roughly the shape of an electric flat-iron with two spear-like flagellæ protruding from the pointed end of the bodies. Their size was very uniform, the bodies measuring roughly 100 microns in diameter, and the flagellæ about 75 microns in length. The flagellæ moved rhythmically, sometimes separately and again in unison. Occasionally the flagellæ would flex themselves until they lay against the body of the parasite. Twice the organism was seen to turn over completely.

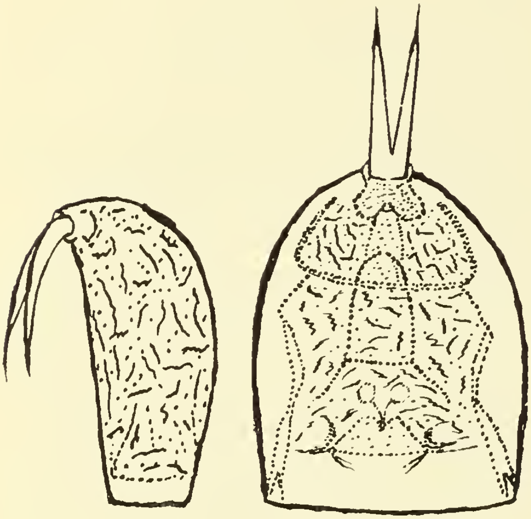

Fig. 1 *(left)*. Antero-posterior view of the parasite.
Fig. 2 *(right)*. Lateral view of the parasite showing the flagellæ flexed onto the body of the organism.

Their activity was marked at first but this gradually diminished, and after about ten minutes ceased entirely.

The parasites were finally identified as a rotifer of the Lecane type. They are notorious as contaminators and are found in stagnant water. Because of the possibility of contamination as a source, great care was taken in the collection of the specimen, using only new sterilized containers and laboratory equipment. In spite of this the organisms still persisted.

We are reporting these findings, realizing that they may still be a contamination, in spite of our efforts in avoiding it, and because we wish to know if any of our colleagues has observed the same phenomenon.

THE PREVENTION AND CONTROL OF VENEREAL DISEASES

A report of considerable interest recently submitted to Congress by Surgeon General H. S. Cumming deals with the prevention and control of the venereal diseases. During the fiscal year recently ended, the state health officers of 43 states reported to the Public Health Service slightly more than a quarter of a million cases of syphilis and more than 150,000 cases of gonorrhea. These diseases as a class continued to exceed the number of cases reported during the year of any other single communicable disease with the exception of measles.—U. S. P. H. S., March 11, 1932.

OF GENERAL INTEREST

Dr. A. B. Stuart, of Cloquet, Minnesota, addressed the Young Men's Forum of Cloquet Wednesday evening, March 9, on "The Menace of Medical Socialism."

Dr. Myron O. Henry, Minneapolis, talked before the Douglas County Medical Society at Superior, Wisconsin, March 2, 1932, on "Fractures of the Hip."

Dr. W. W. Duke of Kansas City, Missouri, addressed the Hennepin County Medical Society on "The Dawn of a New Specialty in Medicine—Allergy," Wednesday, March 2.

Dr. H. G. Irvine of Minneapolis was elected grand primarius of Alpha Kappa Kappa, national medical fraternity, at the concluding session of their three-day convention in New Orleans recently.

Dr. Ehrling L. Bergquist, son of Mr. and Mrs. E. L. Bergquist, Minneapolis, a graduate of the medical school of the University of Minnesota, class of 1929, and Miss Gertrude Babcock, daughter of Mr. and Mrs. M. Babcock, of Fairfield, Connecticut, were married at the home of the bride Saturday, March 5.

The 1932 Committee on Public Health Nursing for the State Association is to be headed by Dr. Harry Oerting, St. Paul. Other members are Dr. George Earl, St. Paul; Dr. C. B. Wright Minneapolis; Dr. H. I. Tregilgas, South St. Paul; Dr. W. H. Eude, Minneapolis; Dr. T. C. Flynn, Redwood Falls; and Dr. C. E. Caine, Morris.

Dr. Kenneth Bulkley is the new president of the Minneapolis Surgical Society elected at the Hennepin County Medical Society headquarters March 3. Other officers chosen are Dr. Martin Nordland, vice president; Dr. F. A. Olson, secretary-treasurer; Dr. R. C. Webb, council member for a five-year term, and Dr. E. A. Regnier, council member for a four-year term.

Hutchinson Community Hospital has been bequeathed $10,000 by L. A. Ritter as a trust fund, the net income from which is to be used for medical, surgical and nursing care for deserving persons who may from time to time be patients therein. Trustees of the funds are the Farmers and Merchants State Bank and the president of the hospital association.

Dr. and Mrs. J. F. McClendon and their sons, Stewart and John, Minneapolis, sailed March 24 on board the Asama Maru for the orient. Dr. and Mrs. McClendon and sons will make their home in Sendai, Japan, where Dr. McClendon will be associated with the Tohoku Imperial University as a visiting professor. Dr.

McClendon is a professor of physiology at the university.

April is the month chosen each year by the National Tuberculosis Association for its intensive campaign in the tuberculosis fight. This year its slogan is "Find the Other Case." A special pamphlet, "Where is the Other Case " has been prepared by the Association for physicians and is available upon request (without charge) at the Minnesota Public Health Association, 11 West Summit Ave., St. Paul.

Dr. Mario McC. Fischer, secretary of the St. Louis County Medical Society, is Duluth's new public health director, having been appointed, effective March 15, by the safety commissioner, Warren S. Moore. He succeeds Dr. L. A. Sukeforth, who resigned in December after eight years of service. Dr. Fischer will be employed full time. He is a graduate of the University of Minnesota medical school.

Contagious disease cases in the city of Duluth in the future will be cared for at St. Mary's and St. Luke's hospitals, and the municipal contagious hospital at Thirteenth Avenue west will be closed, under approval given by the city council at a weekly meeting held March 7. The council accepted the bids of the two hospitals to care for patients. The plan was recommended in a survey made by a government health director of that district.

"Pioneer Medicine in the Western Reserve," a book written and illustrated by Cleveland physicians, was published early in March by the Cleveland Academy of Science. The book relates in colorful detail the early medical history of Ohio. Among those who collaborated in the preparation of the book are Howard Dittrick, Frederick C. Wait, R. C. Rosenberger, J. Richey Horner, Edward Spease, Thomas J. Hill, Marion Noville Gibbons, J. P. Sawyers and Joseph T. Smith, Jr.

Sanction of the Council of the Minnesota State Medical Association was given at its last meeting for a survey of cancer statistics of Minnesota to be undertaken under the auspices of the American Society for the Control of Cancer. The committee of the state association appointed by Dr. M. S. Henderson to cooperate with the representatives of the cancer society includes Dr. H. E. Robertson, Rochester, chairman; Dr. Arthur Collins, Duluth; Dr. J. C. Litzenberg, Minneapolis; and Dr. John Rothrock, St. Paul.

The completed roster of members and officers of all the component societies of the Minnesota State Medical Association will appear in the May issue of Minnesota Medicine, after which time reprints will be available. This roster goes to every county attorney, every probate judge and most of the Insurance Companies in Minnesota for their use, identification and selection of medical service. Only those members whose dues have been paid and whose names have thus been forwarded to the state office before April 12, the publication date of the roster, will appear in this official list for 1932.

Dr. Leonard G. Rowntree, now director of clinical investigation of the Mayo Clinic, Rochester, Minnesota, and professor of medicine in the University of Minnesota, will head the new Philadelphia Institute of Medical Research, it has been announced.

The institute will center its activities in the Philadelphia General Hospital and will work with the various medical schools already established in the city. The new organization will be developed along the lines of the famous Pasteur Institute in Paris and the Rockefeller Institute for Medical Research in New York.

One hundred and twenty-five medical men, including staff members of the Charles T. Miller Hospital, were guests at a dinner given by the hospital in honor of Dr. John L. Rothrock Tuesday night, March 1, 1932.

Dr. Rothrock addressed the group on "Medical Progress in the Last Forty Years." Dr. Rothrock, famed as an obstetrician, has practiced in St. Paul for more than forty years. In December, 1931, he announced his intention of retiring, but he has been called on to continue his services and now expects to give up his practice gradually.

Dr. H. Kyuno, director of the Municipal Tuberculosis Sanatorium at Yokohama and a distinguished Japanese expert on tuberculosis, visited sanatoriums for treatment of the disease in and near the Twin Cities March 4, as part of a world tour on which he is studying such institutions.

As the guest of the Ramsey County Public Health Association, he visited Ancker Hospital and the Ramsey County Children's Preventorium in St. Paul.

He also inspected the Lymanhurst School for Tubercular Children in Minneapolis and Glen Lake Sanatorium at Oak Terrace before leaving for Chicago Friday night. He will sail from New York soon and expects to return to Yokohama in August.

The University of Minnesota, Carleton College and St. Olaf College share the wave length of 1,250 kilocycles with the commercial station WRHM. The three educational studios together use twenty hours a week and WRHM 104 hours. WRHM has petitioned the Federal Radio Commission at Washington to give them the entire time on this wave length. As a countermove the three educational institutions, claiming that the two commercial stations, WCCO and KSTP, furnish all the commercial broadcasting necessary in this area, have now petitioned the Federal Radio Commission to give the three colleges the entire time on this wave length. As radio listeners know, WRHM carries obnoxious advertising such as invitations for free medical examinations, and the medical profession of Minnesota is requested to write the Federal Radio Commission, Washington, D. C., protesting any curtailment of the use of 1,250 kilocycles by the educational institutions mentioned.

Dr. L. R. Critchfield, 1932 chairman of the Public Health Education Committee, reported on the scope of the work of his committee and on its program for the year at the regular February meeting of the Committee Chairmen of the State Association held Monday, February 29, at the Minnesota Union, University of Minnesota.

In the absence of Dr. M. S. Henderson, Rochester, president of the Association, Dr. E. A. Meyerding, St. Paul, Secretary, presided. Dr. C. B. Wright, Minneapolis, reported on the sessions devoted to the discussion of hospitalization and medical care of veterans held in connection with the Congress on Medical Education and Licensure in Chicago. The following chairmen and officers were present: Dr. Critchfield, Dr. W. H. Hengstler, Dr. John H. Armstrong, Dr. Leo Rigler, Dr. J. A. Watson, Dr. Gilbert J. Thomas, Dr. T. H. Sweetser, Dr. N. O. Pearce, Dr. S. R. Maxeiner, Dr. Wright and Dr. Meyerding.

Dr. and Mrs. J. A. Watson, Minneapolis, and their son, James Watson, Jr., will sail April 5 for a trip abroad. They will land at Naples, Italy, where their daughter, Miss Elinor Watson, who is studying music at the University of Munich, will meet them. Dr. and Mrs. Cecil J. Watson, son and daughter-in-law of Dr. and Mrs. Watson, may also meet the travelers in Naples. Dr. Cecil Watson is doing research work at Munich as a fellow from the national research council of Washington.

Munich will be the headquarters of the party and they will take short side trips to Vienna, Budapest and other cities following their drive northward from Naples to Munich. Dr. and Mrs. Watson and James, Jr., will visit in France and Switzerland before going to England, where they will visit another son, Mr. Leland Watson, a Rhodes scholar at Oxford university. They will visit in Ireland before returning to the United States about the middle of June.

COÖPERATIVE CLINIC TOURS

Arrangements have been made by the various State Medical Journals with the Amerop Travel Service for members to obtain at a very reasonable figure Clinic Tours to Europe this summer. The Centennial Anniversary meeting of the British Medical Association affords a special attraction this year. Clinics by outstanding members of the profession in Europe are being arranged in many of the principal cities of Europe, which include London, Paris, Vienna, and Berlin.

The steamers chosen are the palatial Bremen and Europa of the North German Lloyd Line and the best hotels will be used for those travelling first class.

Tour 1.—Leaves New York on the Bremen June 7, arriving at Cherbourg June 12. Thence to Paris, Berne, Lucerne, Zurich, Munich, Vienna, Prague, Dresden, Leipzig, Berlin, Amsterdam, The Hague, London, leaving Southampton July 29 on the Europa and arriving in New York August 3. Price first class $1,215; tourist $894.

Tour 2.—Leaves New York on the Europa July 19, arriving at Southampton July 24, thence to London, The Hague, etc., reversing the route of Tour 1, sailing from Cherbourg September 2 and arriving at New York September 7. Price: first class $1,095; tourist $774.

Tour 3.—Leaves New York on the Europa July 19. Only London and Paris clinics arranged for, with return to New York August 12 on the Bremen. Price: first class $760; tourist $365.

A deposit of $50 is required for reservation with return in full upon notification at least four weeks prior to sailing. Checks may be sent to the office of MINNESOTA MEDICINE or direct to Amerop Travel Service, 132 North LaSalle St., Chicago.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

FORMER NATUROPATH PLEADS GUILTY TO PRACTICING HEALING

State of Minnesota *vs.* Mitchell Jurdy

"Dr." Mitchell Jurdy, listed in the 1931 Minneapolis City Directory as a Naturopathic Physician, entered a plea of guilty to practicing healing without a Basic Science Certificate, on February 19, 1932, before the Hon. Frank E. Reed, Judge of the District Court at Minneapolis. Judge Reed sentenced Jurdy to a term of one year in the Minneapolis City Workhouse and stayed the sentence for one year pending the good behavior of the defendant and his compliance with the Medical Laws of this State.

Jurdy formerly maintained an office at Seventh and Hennepin in the City of Minneapolis and later practiced in his home at 3104 Portland Avenue. The present charge against Jurdy is based upon the alleged treatment of one Ruth Kleopfert, who, it was claimed, had been suffering for some time from epilepsy. Mr. Kleopfert, father of the patient, testified that they met the defendant at the Riley Long Life Health Club where Jurdy lectured. On the date of his sentence Jurdy told the representative of the Minnesota State Board of Medical Examiners that he has severed all connections with the Naturopathic Organization. The defendant is a young man about 28 years of age, married and the father of one child, his home formerly being in the State of Idaho.

DULUTH HEART "SPECIALIST" PAYS ONE HUNDRED AND FIFTY DOLLARS FINE

State of Minnesota *vs.* Hansen.

Harry A. Hansen entered a plea of guilty to practicing healing without a Basic Science Certificate on March 9, 1932, before Judge Edwin J. Kenny of the District Court in Duluth. After admonishing the defendant to comply with the Medical Laws of this State and informing him that a second violation of these laws would result in a straight Work-farm sentence without the opportunity to pay a fine, Judge Kenny imposed a fine of $150, which the defendant paid.

Hansen is 58 years of age and for the past four years has been doing business at 1906 West Superior St., Duluth, as the maker of "Master Medicines." He has been specializing in the treatment of heart ailments, tuberculosis, ulcers of the stomach and rheumatism. Prior to that time he was located at Ashland, Wisconsin, where he did similar work. The investigation also discloses that at one time he was an extra man on the Ashland Police Department. Hansen informed a representative of the State Board of Medical Examiners that he had the only cure in the world for tuberculosis which he was selling for $3.00 per two ounce bottle. People would go to Hansen's office where he would discuss with them their symptoms and he would then recommend his preparations. He charged $5.00 per two ounce bottle for his heart medicine. Hansen claims to have no medical education nor has he studied pharmacology except that obtained from reading books in his office. He claims to have his knowledge bestowed upon him in answer to a prayer.

DULUTH QUACK SENTENCED TO WORK-FARM

On March 4, 1932, John F. Kroeten, 48 years of age, entered a plea of guilty to practicing healing without a Basic Science Certificate before the Honorable Edwin J. Kenny, Judge of the District Court at Duluth. Judge Kenny sentenced the defendant to serve three months on the St. Louis County Work-farm. The Court refused to suspend the sentence and as a result thereof Kroeten must spend the next three months on the St. Louis County Work-farm.

Kroeten is an itinerant quack who has attempted to practice healing in St. Paul, Minneapolis and Eau Claire, Wisconsin, without the "formality" of obtaining a license. He is a carpenter and painter by occupation. He claims to have obtained his knowledge in the healing arts from other members of his family. Kroeten was arrested February 24, on complaint of the State Board of Medical Examiners, and was confined to the County Jail until March 4, because of his inability to furnish $500 bail. Some of the ailments Kroeten claimed to be able to cure were varicose veins, running sores, blood poison, rheumatism and "cancer on the outside."

This is the first prosecution for violation of the Medical Laws in St. Louis County in the past year and the Court by imposing a straight Work-farm sentence has made it very plain that quackery will not be tolerated in that County. Splendid coöperation was also received in this case from Harry E. Boyle, County Attorney, T. J. Naylor, his assistant, and the Police Department of the City of Duluth.

THE ADMINISTRATION OF SUPRARENAL CORTICAL EXTRACTS

The efficacy of replacement therapy in cases of Addison's disease by the injection of suitably prepared extracts of the suprarenal cortex, freed as far as possible from the epinephrine liberated by the medulla of the gland, has apparently been established. For patients that tolerate intramuscular injection well, this is, perhaps, the preferable method of administration. The intravenous method is indicated when the patient is in crisis and an immediate response is necessary. The possibility of effective oral administration has recently been reported on. In cases in which prolonged treatment is demanded, the oral route may be of preferential utility. (Jour. A. M. A., January 2, 1932, p. 52.)

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of April will be as follows:

April 6—Personal Hygiene—Rest and Sleep.
April 13—Leg Cramps.
April 20—When Pneumonia Begins.
April 27—Spinal Cord Tumors.

AMERICAN PROCTOLOGIC SOCIETY

The thirty-third annual meeting of the American Proctologic Society will be held in Memphis, Tennessee, on Friday and Saturday, May 6 and 7, 1932. Headquarters will be at the Hotel Peabody. The program includes clinics, and scientific papers. All interested members of state medical associations upon the payment of the usual fee of $5.00 are eligible to attend the session which has been arranged to convene immediately preceding the A. M. A. meeting at New Orleans, May 11.

WOMEN'S AUXILIARY

Minnesota State Medical Association

President—Mrs. James Blake, Hopkins
Chairman Press and Publicity—Mrs. Glen R. Matchan, Minneapolis
Editor—Mrs. Horatio B. Sweetser, Jr., Minneapolis

CAMP RELEASE MEDICAL AUXILIARY

Mrs. R. C. Adams, Bird Island, president of Camp Release Medical Auxiliary, announces the following appointments of Public Health Chairmen for the Camp Release district: Renville County, Mrs. A. A. Passer, Olivia; Yellow Medicine County, Mrs. J. Kilbride, Canby; Chippewa County, Mrs. L. G. Smith, Montevideo; Lac Qui Parle County, Mrs. Nels Westby, Madison.

RAMSEY COUNTY

At the regular meeting of the Ramsey County Auxiliary at the home of Mrs. K. C. Wold, January 25, a silver cup was awarded to Robert Laurason of Harding High School for the best paper on "Cause and Prevention of Tuberculosis." Mr. Paul Fesler gave an interesting talk on the "Hospitalization of Veterans of the World War."

On February 12 a party was given at the Ramsey County House for the inmates. From the progressive card party also held during February, a substantial sum was realized to be used toward the Student Loan Fund.

HENNEPIN COUNTY

The February meeting of the Hennepin County Auxiliary was held Wednesday, February 24, in the Society rooms, where a program inspired by the Washington centennial was greatly enjoyed.

At the annual meeting and election of officers of the auxiliary held March 23, at 10:00 A. M., in the Nicollet Hotel, Minneapolis, the following officers were elected:

President, Mrs. Hugh Tunstead; president-eleet, Mrs. F. A. Erb; first vice president, Mrs. Emil Geist; second vice president, Mrs. Moses Barron; recording secretary, Mrs. G. T. Nordin; corresponding secretary, Mrs. H. B. Sweetser, Jr.; treasurer, Mrs. George G. Eitel; auditor, Mrs. Glenn Matchan; custodian, Mrs. H. W. Quist.

A class for the study of international relations has been organized under the very able leadership of Mrs. Walter Marcley. This class is open, without charge, to any members who care to attend the meetings.

PROCEEDINGS OF THE MINNEAPOLIS SURGICAL SOCIETY

SYMPOSIUM ON FRACTURES

Conducted Jointly with the Minneapolis Regional Sub-Committee of the General Fracture Committee of the American College of Surgeons
Meeting of Wednesday, February 3, 1932
Auditorium of the Medical Arts Building, Minneapolis
Dr. J. Frank Corbett, Presiding

Dr. J. Frank Corbett: As President of the Minneapolis Surgical Society, I have been requested to call this meeting to order. After a few general statements have been made the conduct of the meeting will be turned over to Dr. Kenneth Bulkley, Chairman of the Minneapolis Regional Sub-Committee of the General Fracture Committee of the American College of Surgeons.

There has been a tendency in this locality for general surgeons to neglect fracture treatment, possibly because of the lure of abdominal surgery. This is not true to so great an extent in other places, as the work of Scudder, Speed, Stimson, Blake, Ashurst, Bohler and other general surgeons in recent times demonstrate. The early fundamental principles of bone repair and of fracture treatment were largely in the hand of general surgeons; notably with Murphy, Senn, Parks, MacEwen, Ashurst, Cheyne, and Burghard, Lister, Brandenheuer, Trendelenberg, Bunger, Dawbam, Handley, Freeman, Konig, Lane, Langenbeck, McBurney, and Cotton. More recently the diligence in publishing and the scientific efforts of Robert Jones, Albee, Whitman, Hibbs have made the impression that fractures were an orthopedic problem.

It is manifestly impossible that all fractures could be treated by the relatively few orthopedic men available. This problem is still a duty of the general surgeon. The purpose of this meeting is to make general surgeons fracture minded. It is hoped that the general surgeon will see that he ought not to neglect this field. This entails interest in the subject, careful study, and the solution of problems that are still unsolved. The field is enormous and can not be discussed in a few minutes except in a general way. This will be gone into in more detail by those who follow me. Unless treatment is manifest and some fruits of this interest are developed, the treatment of fractures will pass from the realm of the general surgeon.

Dr. Kenneth Bulkley.—In 1912 the American College of Surgeons was incorporated; in 1913 it emerged from its swaddling clothes and since then has rapidly progressed to young manhood. Among its major achievements the most prominent unquestionably has been its work in the betterment of hospitals through its Hospital Standardization Committee. More recently it has turned its attention to another fertile field—namely the betterment of the care of fractures. In order to carry on this work it appointed what is known as the General Fracture Committee of the American College of Surgeons. This Committee, realizing that it could not carry out its program of improvement in the treatment of fractures, both from the education of the undergraduate and of the graduate, organized in the larger centers of population in this country Regional Sub-Committees to assist it in carrying on this work. My old friend Dr. Charles L. Scudder of Boston, with whose classic book on fractures you are all familiar, is chairman of the General Fracture Committee of the College. Failing in his usual good judgment, he appointed me Chairman of the Minneapolis Regional Sub-Committee on fractures. I have asked to serve with me on this committee one representative of each of the accredited hospitals in Minneapolis and have added to this group a number of other surgeons who for want of better appellation might be termed free lances. Our meeting tonight and our meetings tomorrow are the first fruits of the efforts of this Minneapolis Committee.

We are fortunate in having here in the Twin Cities a member of the General Fracture Committee of the College. The last meeting of the General Committee was held in Chicago in January, 1932, and I take great pleasure in introducing Dr. Roscoe C. Webb, our local member of that General Committee, who will report to us in brief the proceedings of this last meeting.

Dr. R. C. Webb.—The Committee on the Treatment of Fractures of the American College of Surgeons was established by the Regents of the College to promote interest and general improvement in this increasingly important branch of surgery. The great advances in the standardization of the other branches of surgery during the past forty years have so interested surgical teachers that until recently the teaching of fractures has suffered. The sad story of fractures is being constantly related before our industrial commissions, when the victim is so fortunate as to have had his accident while employed, and the permanent disability ratings granted and the computations of costs in money make up a large portion of the commission's reports.

The American College of Surgeons' Year Book contains the reports of the Committee on the Treatment of Fractures and you have no doubt noticed that the fundamentals such as the teaching of fractures in medical schools, the minimal equipment for hospitals, accepted treatments for certain common fractures, the organization of regional sub-committees, and similar subjects have been included in these reports. The Committee functions through annual meetings of the Committee, through sub-committees, and through regional sub-committees.

The annual meeting of the General Fracture Committee of the American College of Surgeons was held early in January of this year in Chicago at the College of Surgeons building. The meeting was similar to our meeting now being held, in that it covered two days and consisted of reports of committees combined with clinics at the University of Chicago by Dr. Phemister and at the Presbyterian Hospital by Dr. Speed.

The Committee on Bone Plates and Screws reported the completion of their work for the present. Surgeons in various parts of the country had reported catastrophes resulting from the breaking of bone plates. Investigation showed that these were due to inferior material in the plates. This committee, in conjunction with the United States Bureau of Standards, has provided standards for manufacturers and certified plates and screws are now on the market.

The Committee on Medical Education in Fractures gave the results of one of the recent questionnaires to medical schools and described the teaching in one of the larger eastern medical schools. In the first year the students receive four hours in instruction on fractures, two hours when the work of dissection on the upper extremity is completed consisting of demonstration of prepared specimens with classical fractures with discussion of the surgical anatomy and the structures which may be injured, followed by illustrations with X-rays and clinical cases. A second similar two hours is given on completion of the dissection of the lower extremity.

In the second year a similar four hours are again given in connection with the studies in anatomy. Also in the second year twenty hours are devoted to fracture healing and pathology in connection with the course in pathology supported by experimental work and clinical cases.

In the third year the students are advised to secure the A. M. A. Primer on Fractures and are given the American College of Surgeons' Outline on Treatment of Fractures. Thirty-seven hours of instruction in fractures are given to small groups in the out-patient department and there are seven hours of instruction in the care of bed fractures.

In the fourth year there are fifteen hours of instruction on the wards in the bed treatment of fractures. In addition surgical clerks spend a few nights in the hospital to see the handling of acute fractures and an attending surgeon is required to come to the hospital for each case for the purpose of teaching initial diagnosis and treatment.

The Committee on Contact With the National Board of Medical Examiners reported that questions on fractures will be included in the examinations in surgery.

Ambulance equipment was also discussed and recommendations were made. It is probable that the ideal here will not be reached until all internes riding ambulances are thoroughly versed in the anatomical structures surrounding the fractures as well as the pathology, and will as a result become first-aid-minded, so to speak.

Physiotherapy was discussed and the opinion was expressed that early physiotherapy should be further developed.

Regional committees were reported upon and their further development was urged.

One session was devoted to work on revision of the Outline of the Treatment of Fractures which was published last spring. It is hoped that this volume can be published in an improved form in the near future.

The Committee on the Treatment of Fractures is now in the tenth year of its existence. The Minneapolis Surgical Society is now beginning its second decade. The coöperation of this society should insure much constructive work by the local region sub-committee in the care of fractures generally in this vicinity.

THE TEACHING OF FRACTURES IN THE MEDICAL SCHOOL CURRICULUM

Dr. Owen H. Wangensteen

The impetus lent to surgery by its three greatest benefactors—anesthesia, asepsis and the Roentgen rays— have widened tremendously the borders and increased the scope of surgery. These agents have likewise been a great boon to the better and more intelligent handling of fractures. Everywhere, however, one hears echoed the criticism that fracture treatment has not exhibited the uniform improvement long since manifest in many newer chapters of wound management. Many who are qualified to know and have given the matter serious study say that fractures on the whole are badly managed.

Amongst other causes, one naturally seeks an explanation of this existing state of affairs in the curriculum of the medical school where the future practitioner establishes his first contact with the conduct of fracture cases. If one were to direct his inquiry concerning the teaching of fractures to the deans of our medical schools or subordinate officials more directly responsible for this subject, he probably would receive a fairly uniform type of answer. They would probably be the first to own that fractures like most other subjects in the curriculum do not receive the attention that the importance of the subject justifies. In event the interrogation came when the deans and their curriculum committees were brooding over contemplated increases in allotment of time to any of the divisions (a no small part of the Deans' worries) and the utter futility of adjusting the curriculum to everyone's complete satisfaction was quite apparent, the apology concerning the inadequacy of instruction in fractures might be qualified to this extent: The chief office of the medical school is to equip the student with weapons with which he may intelligently approach his future problems. Medical training is a life-long process of education in which the young graduate has made only a start. The Medical School believes that if it has taught its students how to think that it has served its purpose well. We have sought to stimulate their interest and arouse their curiosity but not to satisfy it. We have not made finished artisans out of our students but we have furnished each with tools with which through constant effort he may become practised in their use.

The advent of cellular pathology which has contributed in such large measure to our better understanding of disease processes has stimulated a great interest in normal as well as pathological microscopic anatomy with a consequent lessening of intensity of interest in applied anatomy. Our predecessors who were called upon to reduce fractures without the aid of anesthetics were far better schooled in the knowledge of muscle antagonists than we. They were intimately concerned with the art of obtaining relaxation of the muscles responsible for the deformity. Though anesthesia has modified the problem greatly, I am persuaded that a good grounding in applied anatomy is just as essential today in the management of fractures. A knowledge of the mode and extent of muscle pull contributes definitely to a better understanding of the occurrence of fractures through the most frequent agency of indirect violence.

Zuppinger went to the anatomical laboratory in Zürich to investigate the force necessary to break the tibia by twisting. The laboratory "diener" informed him that he had taken over a very difficult task. It was found that four men could not break the tibia in this manner even though the foot was twisted off at the ankle joint. Sir Astley Cooper relates that when Damien was executed for the attempt to murder Louis XV, four horses were fixed to his legs and arms, and repeated ineffectual forced attempts for over fifty minutes were made to tear his limbs from the body. In order to effect this dismemberment and extinguish the doomed man's life, the executioners were obliged to cut the muscles and the ligaments near the trunk. The agency of muscle pull determines in large measure the facility with which fractures are seen to occur. Dislocations and fractures are more readily sustained in life than after death.

At the University of Minnesota two formal required courses in fracture instruction are given; one is an objective course of eleven sessions, each of an hour and a half in length in which cases are shown demonstrating the particular varieties of fractures under discussion. This course is given to the juniors, one division of the junior class being present each quarter. Two of the eleven weeks of the surgical clerkship offered to seniors is spent solely on fractures. Both these courses are given under Dr. Zirold's supervision at the Minneapolis General Hospital where an abundant fracture material is available and he is here to speak more in detail about the nature of this instruction.

Fracture instruction is also imparted, though in a lesser degree, in the courses of applied surgical anatomy, principles of surgery, regional surgery (orientation course), lectures on orthopedic surgery, the weekly clinics to juniors and seniors, the surgical Out-Patient Clinic, and in ward walks with the surgical clerks by the hospital staff.

There exists a large mass of knowledge concerning fractures, but one can not escape the impression that this information is not as well crystallized as that in other spheres of the surgeon's activity. The fundamentals of fracture treatment, viz., reduction, fixation, and assurance of good function need more emphasis. He who essays to treat fractures must learn to be the master of a method and not the slave of apparatus. Patients are not infrequently admitted to the hospital some days after the occurrence of a fracture with the note that the proper splint or apparatus was not available for handling it.

A stimulation of interest in fractures will undoubtedly contribute more to their management than any other combination of factors. With an increased field of activity has come a lessened interest in fractures and a tendency on the part of accomplished surgeons to turn this time-consuming group of cases over to their less experienced associates. Surgery is not a province with fixed boundaries. With advances in knowledge, some diseases once dealt with almost solely by operation are found to respond better to more conservative means of treatment, while others for similar reasons are surrendered by the internist to the surgeon. That which is essentially mechanical, however, has always remained surgical. Wound surgery, of which fractures constitute an essential part, has ever been the surgeon's domain. Whether fractures will remain a field of activity for the general surgeon or be taken over in large measure by reprisal by the industrial or orthopedic surgeon, the general surgeon's interest will chiefly determine.

Fractures constitute so great a portion of the injuries and accidents that it is highly important that a large number of well qualified individuals be prepared to deal with this important branch of surgery. The general practitioner has always been an important agent in the caring for fractures and his interest in an improved fracture program must be enlisted. In the care of those fractures in which the responsibility is great he should be counselled to seek skilled aid in their management from the start.

The recent graduate casting about for a field in which to divert his interest and equip himself by special training in surgery is not likely at present to become enthusiastic over fractures. He knows that the care of fractures demands constant attention and eternal vigilance and that the rewards of his labors in terms of hours spent is not great. He knows that his liability to a charge of malpractise is much greater in external injuries than when dealing with obscure internal complaints. Though mindful of the correlation between anatomical restoration and function, he sees juries placing undue emphasis upon the X-ray film. He hears of cases not settled on their merit but by debate in which physicians express seriously conflicting opinions over matters in which he sees little room for disagreement. He notes that unprincipled colleagues and unscrupulous lawyers will for a fee distort facts and confuse issues that lead to a decision in which he sees no justice, and may even prove his undoing.

Possibly these are some of the evils that must be patiently tolerated temporarily but which will in the end clear some of the barriers and bring about the reform that must take place before young men will lend themselves wholeheartedly and without prejudice to this important chapter of surgery.

FRACTURE TEACHING AND ORGANIZATION AT THE MINNEAPOLIS GENERAL HOSPITAL

Dr. A. A. Zierold

The Minneapolis General Hospital has approximately 768 beds available for the service of charity patients. Of this, the surgical service comprises about 150 beds. Some fifty to ninety beds of these are usually given over to fracture cases. This constitutes a separate and distinct division of the surgical service and is administered and staffed as such. In the receiving wards there are fourteen to fifteen beds for such patients as require a short period of observation, but whose condition does not demand admission to the surgical wards. Added to this, the daily out-patient service admits the ambulatory cases for after treatment and physiotherapy.

The staff consists of a chief and three associates which change every three months. Of the attending staff one man is assigned to the fracture service and he and the chief constitute the senior staff of the service. It will be necessary to go a bit more into detail concerning the fellowship teaching and staff. We have, at present, five teaching fellows on the surgical service. At the end of six months we expect to have six. These are residents of the surgical service and are appointed for a period of three years. During the first six months of their residence, they are assigned to general surgical service with the duties of a first assistant and the responsibilities of the care of surgical patients. The second six months period is spent on the fracture service both in the hospital ward and in the out-patient department. During the third six months, the assignment comprises the orthopedic service and the receiving service combined. The fourth six months is made up of a similar receiving service combined with urology. At the beginning of his third year, the teaching fellow occupies the position of junior resident and is allowed to do minor surgery and such supervised operating as lies within his capacity as determined by the attending surgeon. During the last six months the teaching fellow as senior resident is permitted to do independent operating and to have the care of such cases as may be determined by the attending staff. During this last year the junior and senior residents act as advisors and supervisors of the men who are their juniors.

The interne organization as applied to surgery is composed of four men on a rotating service. Two of these men are assigned to fractures, and together with these two is another interne who is on a straight surgical service and who remains for six months on fractures and six months on general surgery.

The receiving service is staffed by one of the senior fellows and one of the senior residents who has passed through his general surgical service and through his fracture service, and who has at his disposal the attending staff man assigned to the service at that time.

The out-patient service up to recently has been cared for by teaching fellows, internes, and an assigned staff man. This will probably be changed with reorganizations of the dispensary and the out-patient staff. The department of physiotherapy is in the charge of a full time physiotherapist who cares for the patients within the hospital and such out-patients as require treatment.

Briefly, the fracture service is a distinct division staffed by the chief, associates, senior and junior fellows, and junior and senior internes.

The teaching of fractures to the students is undertaken both by lecture and by clinical demonstration. There are weekly lectures of one and one-half hour each in which bone injury, repair, methods of treatment of typical regional fractures, complications, and results are considered. These lectures are supplemented by individual case record, X-ray examination, and exhibition of illustrative cases. If the patient cannot be moved, the students are taken to the wards to inspect the case, its progress, and the manner of treatment. Following the completion of the assigned course of lectures, the student is assigned to a clinical clerkship devoted solely to fractures. This occurs during the senior year. During the time of a student's assignment, he is required to take case histories, make physical examinations, and observe and record the progress and treatment of his cases. Each day the student group is met by a staff man and some particular phase of fractures is taken up in the form of a clinical demonstration. Fractures are seen, too, by the student in the receiving ward and emergency calls are responded to as in other clerkships. Although no organized course of physiotherapy is given, an attempt is made to have the students observe the various forms and applications of physiotherapy. The surgical service and particularly the fracture service has been in a state of flux from out of which is gradually crystallizing a definite organization. I feel that it would only be fitting at this time to express a most heartfelt appreciation for the work of Dr. Charles Remy as superintendent of the Minneapolis General Hospital. By reason of his understanding and capacity for organization and accomplishment, not only the physical equipment of the hospital, but the morale of the personnel is at a higher point than ever before. This has been supplemented by the coöperation of Dr. Wangensteen who has afforded us a generous number of teaching fellows of most excellent quality.

Dr. Emil S. Geist discussed "The Minimal Requirements of the Average Hospital For the Care of Fractures," with the following conclusions:

A. Fractures can be, and have been, well taken care of with extremely meager physical equipment, if the surgeon possesses brains, training, ingenuity, and mechanical fitness.

B. The most luxurious mechanical contrivance will not itself cure a fracture; it must be under the constant and intelligent control of the surgeon or of the orthopedic surgeon.

AMBULANCE EQUIPMENT AND PERSONNEL

Dr. Edward T. Evans

My assignment, "The Equipment Necessary for the First-aid Treatment of Fractures," assumes, I suppose, that I should speak of physical equipment.

I prefer to go further back in the treatment of our largest single industrial and machine-age accident result.

The old-fashioned bone setter treated many serious fractures as well and often better than some of us. They, at least, had instinct and mechanical sense on their side.

My contention is that all the physical equipment in the armamentarium of the most renounced fracture man is useless in the hands of a recent graduate or interne or country practitioner or general surgeon, unless he has that fundamental mechanical sense which tells him how to utilize it. And our specialists become dangerous when their armamentarium directs their method of treatment.

We have assembled here during these few days, not to improve ourselves alone, but to shape future policies with regard to fracture care in this district with the hope that we may mould others into the same line of thought. That means teaching,—a thankless task. Of course we have our brilliant student who follows our lead, who looks up to us and adopts our ways (perhaps that is why we think him particularly brilliant); but the average student is not so. Him we must so teach and direct that he develop a mechanical sense, a fundamental anatomical and functional understanding, and a stick-to-it-iveness that will follow his fracture through from the first aid to recovery. And we must instil in him the realization that sometimes his physical and mental equipment is insufficient and he must realize when he is over his head and should call for assistance.

I regret that my work leads me to the above conclusion. Not in a spirit of criticism but rather in an attitude of facing the facts and trying to drive home this thesis, I cite the following:

The first fracture I saw in this city was a subtrochanteric fracture treated first in a poorly fitting plaster spica by a man who could not use plaster (the first lesson a fracture interne should learn and it takes at least a month of daily plaster work to do so); then by skin traction which was inadequate at four weeks when it was applied. Open reduction was done the day following the removal of skin traction—in the presence of blisters. The patient died of osteomyelitis and amyloid degeneration after months of suffering.

I recently saw a traction of forty pounds applied to a Steinman pin in the os calcis for an old fractured shaft of the femur with two and one-half inches overriding. Luckily the pin broke before the ankle and knee ligaments. The patient now has Kirschner pin traction through the femoral condyles with satisfactory reduction.

A fracture of the surgical neck of the humerus recently came under my observation. The fracture is beautifully reduced but the patient has lost two-thirds of her elbow motion from a Steinman pin insertion in the olecranon process.

A fracture at the base of the neck of the femur in a man of thirty-eight is now under my care with three and one-half inches over-riding and non-union because the spica was removed at seven weeks. The reduction was perfect, but the plaster had to be removed because a check-up X-ray showed the fracture had slipped in the plaster. Need I comment on that plaster?

A week ago I reduced an old Colles' fracture with terrific deformity which occurred in a man with a fracture of the neck of the femur. The Colles' fracture was not recognized. The neck of the femur was treated in a short leg spica, to above the knee!

These are extreme cases I admit, but as I look back over them I know that they were avoidable if we, as teachers, and this includes you older men who taught us younger ones, administer first-aid in the class room, the anatomy laboratory, the clinics, and then on the street and accident floor where the physical first-aid of the fracture commences.

What then are these physical agents for use in the first-aid treatment of fractures? Let me enumerate them briefly.

1. The fracture conscious interne.
2. Stretcher.
3. Warm blankets.
4. Tourniquet.
5. Sterile dressings and elastic bandages.
6. Four triangular muslin slings.
7. Four muslin bandages four inches wide.
8. Thomas ring splint for leg.
9. Thomas ring splint for arm.
10. Large soft pillows.
11. Basswood boards 30 × 4 × ¼ inches.
12. Safety pins.

Of all the above the Thomas splint is by far the most important and most useful, the use of which every interne should thoroughly understand. In an attempt to impart some conception of its usefulness, Dr. Wallace Cole devoted two full periods of senior lectures to this subject alone.

Do's:

1. Treat shock by keeping the patient warm and stopping hemorrhage, preferably by compression bandages.

2. Use the tourniquet without hesitation if necessary.

3. "Splint them where they lie" without moving them about.

4. Use the Thomas ring splint for all fractures above the middle third of the lower leg and above the mid-shaft of the humerus, using the wide muslin for applying traction as a double sliding loop.

5. Use the pillow and basswood boards applied as a box splint for the lower leg and ankle fractures.
6. Use a double triangle sling for elbow and lower arm fractures.

Don't:

1. Hurry.
2. Be rough.
3. Forget your tourniquet.
4. Forget your fundamental anatomy and physiology.

I plead for mental equipment, applied anatomy, applied common sense, applied follow-up and teaching in our hospitals by those who, by instinct and training, love fracture work and can so carry it out that it will prove an inspiration to our students, be they undergraduate or post-graduate like ourselves.

Dr. Myron O. Henry presented the subject of "Treatment of Fractures of the Vertebræ," with the following conclusions:

1. Any back injury may be a fracture, therefore X-rays are of paramount importance.
2. Those with back injuries should be transported face downward.
3. Deformity in crushed fractures of the vertebræ can and should be reduced as in other fractures.
4. In cases of fracture of the spine with complete paralysis, laminectomy *may* be indicated in the cervical region, is *usually* indicated in the dorsal region, and is *always* indicated in the lumbar region.
5. Most orthopedic surgeons are agreed that fusion operation offers relief in cases of long standing pain and disability after a compression fracture of the body of the vertebræ.

COLLES' FRACTURE

Dr. George R. Dunn

Colles' fracture, a fracture of the lower end of the radius, is frequently associated with a fracture of the styloid of the ulna, tearing of the ligaments of the wrist between the radius and ulna and faulty position of the radius and ulna at the lower radio-ulnar joint, and poor position of the ulna.

Reduction may be accomplished by any one of the several well known manipulations. X-rays after reduction should show that the angle between the articular surface of the radius and the shaft of the ulna forms an angle of 90° or less. Position may be maintained by anterior posterior moulded splints for about four weeks and in most cases careful movement may be commenced in about ten days under the direction of the surgeon. X-rays should be taken before and after reduction, before removing the splint and before resuming full time work. Reduction is usually indicated.

Conditions which may lead to impairment of function are: (1) conditions of the radial joint surface at the radio-carpal joint, especially irregularity; (2) the inclination of the joint surface at the lower end of the radius (normally 75-80° with the long axis of the radius); (3) position of the lower radial fragment; (4) position of the lower end of the ulna; (5) the condition of the radio-ulnar joint; (6) the amount of ligamentous damage and fracture of the styloid of the ulna.

Fifty cases of Colles' fracture treated by forty-eight different medical men which had been examined and X-rayed were reviewed and tabulated. The table shows:

1. The average disability was 14 per cent in hand and wrist.
2. In 74 per cent of cases the articular surface of the radius and the long axis of the radius formed an angle of over 90° (imperfect reduction).
3. In 26 per cent the angle was 90° or less (good reduction).
4. No disability in 24 per cent.
5. The fracture line involved the radio-carpal articulation in 46 per cent with an average disability of 16 per cent (about average).
6. In 8 per cent the radio-carpal joint surface was rough with an average disability of 20 per cent.
7. In 14 per cent, with about an average disability, the radio-ulnar articulation was not good.
8. In 24 per cent the angle between the radial articular surface and the long axis of the radius was distinctly bad (110-125°), and these cases averaged 22 per cent disability.
9. In 26 per cent of the cases, the angle was 90-75° and these averaged 5 per cent disability.

CONCLUSIONS

1. Colles' fractures are not being efficiently reduced.
2. A good reduction, 90° or less, will average about 5 per cent disability.
3. Poor reduction, angle of 110-125°, will average about a 22 per cent disability.
4. An uneven radio-carpal articulation frequently leads to a high disability, but the mere fact that the fracture involves the joint does not give a poor prognosis.
5. Fracture of the styloid plays little part in the disability except in an occasional case.
6. The position of the ulna, the condition of the lower ulnar articulation and ligamentous injury, all should be given attention but are not the most important factors in determining the ultimate result.

FRACTURES OF THE NECK OF THE FEMUR

Dr. O. W. Yoerg

Fracture of the neck of the femur may occur at any age, but it is essentially one of adult life. It constitutes about one-third of all fractures in persons passed 70.

The weakest part of the femur is the neck. The head receives its blood supply through the ligamentum teres and by circulation in the cancellated structure of the bone. In advanced years the vessels in the ligament practically disappear and the head of the bone must depend almost entirely for its blood supply from the spongy tissue of the neck. It is this lessened blood supply with a rarification of the bone due to advancing age that makes this fracture possible, and so often prevents union from taking place.

We are all familiar with the classical symptoms of a fractured hip. It must be remembered however, that a person may fracture a hip and still be able to walk about. It is always advisable in any injury of the hip in patients past middle life to have X-rays made, preferably sterescopic films. A thorough study of the films must be made, as even on excellent films a line of fracture can easily be overlooked. If a fracture does occur and has not been recognized, and the patient is allowed to be about, a breaking down of the fracture may occur and a definite deformity result.

Probably the most satisfactory method of treatment that we have today is the abduction treatment devised by Whitman. It is true that many fractures do not unite even with this method, but it is generally recognized as the method of choice at the present time, and it has been adopted by the fracture committee of the American College of Surgeons after much discussion and study.

X-rays should be made after reduction and application of the spica cast, and should be followed by further X-rays to check the position of the bones. Frequently the patient looses weight and the cast does not fit snugly, and at the end of four to six weeks a film will disclose absorption of the neck with a marked coxa vara. When this occurs the cast must be removed and other treatment instituted.

The abduction spica cast fixation should be used in most cases of fracture of the femur. It should be used in practically all of the young and middle aged, where the bones are impacted with deformity and where they are unimpacted. It may be used in many of the aged, but will require much care and nursing to avoid complications. Sound judgment should always prevail. An old person alive, even if disabled, may bring much happiness to his children and grandchildren, whereas his passing at the expense of a good surgical result, will bring only sorrow.

CARPAL INJURIES

Dr. Richard R. Cranmer

The most frequent injuries to the carpal bones are anterior dislocation of the semilunar, usually without but frequently with fracture, fracture of the body of the scaphoid and row-on-row dislocation. Dislocation of the semilunar bone can easily be missed unless a lateral X-ray view is taken.

Recent dislocation can be reduced by manipulation under the fluoroscope by hyperextension and then gradual flexion while traction is being exerted on the hand and pressure used over the dislocated bone.

Older cases (three days to a week) usually require volar incision and, after the bone is palpable, the same manipulation as described above.

Some few cases in which the volar ligament is torn, and especially if fracture is present, are best treated by excision of the bone.

Fracture of the body of the scaphoid is the most frequent injury in the carpal region and is best treated by approximation of the fragments if there be any malposition, and the application of a dorsal plaster splint from the base of the fingers to the elbow joint so applied as to hold the hand in slight dorsiflexion and slight ulnar abduction. This should be worn for at least six to eight weeks. Old cases with some absorption of the bone should also be so treated, but the splint should remain on for from four to eight months.

If approximation of fragments is impossible, the proximal fragment should be removed.

The usual mechanism of scaphoid fracture is strain having been applied with the hand in hyperextension or acute flexion. The two carpal rows flex on each other but the scaphoid, being so placed as to interfere with the transverse midcarpal joint line, bears the brunt of the force and breaks.

Row-on-row dislocation can be reduced, in most cases, under proper anesthesia and with adequate traction. Excision of a row of carpals, which has been advocated by some, seems too radical a procedure for this condition.

MEETINGS OF THURSDAY, FEBRUARY 4, 1932

On Thursday, February 4, 1932, Dr. Kellogg Speed, Professor of Clinical Surgery at Rush Medical College, Chicago, was the guest of the Minneapolis Surgical Society.

At 10 o'clock in the morning Dr. Speed conducted Fracture Ward Bounds at the Minneapolis General Hospital. At that time he discussed in detail cases presented to him by the Staff of the hospital. The discussion of each individual case was made in connection with X-rays taken before, during, and after treatment. He commented on the treatment and gave his ideas as to the latest principles of treatment in the individual case. This two-hour period proved to be most fruitful.

At 2 o'clock P. M. Dr. Speed addressed the medical students of the University of Minnesota in the Anatomy Amphitheater. Although the address was primarily for the medical school many visiting physicians attended. His address was on "Unhappy End Results in the Treatment of Fractures." In the course of this discussion he showed numerous X-rays of fractures both before and after treatment. His discussion brought out vividly the errors and mistakes which contribute to unfortunate end results. His talk could well have been entitled the "dos and don'ts" in fracture surgery. It was of more than usual value to medical students and to physicians.

At 6:30 o'clock P. M. the Annual Formal Banquet of the Minneapolis Surgical Society was held in the Nicollet Hotel. Dr. Speed was the guest speaker, and following the banquet, addressed the Society on the subject of "Fractures of the Neck of the Femur."

FRACTURES OF THE NECK OF THE FEMUR

Dr. Kellogg Speed

The subject of my talk tonight is something about the problems encountered in the treatment of fractures of the neck of the femur. You have probably all read the papers by Hey-Groves and Whitman given in London in 1929, covering the subject of fracture of the neck of the femur; and if one has followed Whitman's work on the subject, he is inclined to feel that the last word has been said.

My message to you tonight is to stir up the subject and to see what your reaction is to it. There is possibly something deeper in the study of fractures of the neck of the femur than the mere exercise of the Whitman method of extension, inversion and abduction, and it is these additional points we must study.

The points I wish to make are two: (1) that the conservation of the natural blood supply of the head of the femur must be maintained to hurry any bony healing that is to take place, (2) that the reëstablishment of the old line or a new line of weight bearing trabeculæ in the neck of the femur must be obtained so that the whole limb will function; it being assumed that a first class reduction and proper position has been made and held by a suitable plaster dressing for a sufficient length of time. The time required for full bony union varies from six to twelve months and is aided by exercises of the limb and by judicious use, but not by injudicious weight bearing. If there is too much and too early weight bearing it jeopardizes the situation and may act untowardly. The final results will give bony union with retained blood supply in the head, no absorption of bone and strong weight bearing trabeculæ, but the question is when will it give it; and that is what I want to stir up interest in.

You know there are three or four sources of blood supply in the neck of the femur. These are the blood vessels from the diaphysis, from the epiphyseal arteries, from the periosteum and from or through the ligamentum teres. The blood vessels from the diaphysis of the femur come from the superior nutrient artery. It gives branches that may cross over the epiphyseal plane and enter the head of the bone. Second, the epiphyseal blood vessels enter the head in two directions and the periosteal supply is the richest of all.

These lantern slides show by a graphic method the blood supply of the head of the femur and the periosteal blood vessels in a rather massed group penetrating and passing up toward the head. If one takes a specially injected specimen from the cadaver one finds some of these diaphyseal vessels passing across the epiphysis into the neck and head of the bone, giving a rather rich blood supply in the head as a whole.

In the Whitman method of reduction of fracture of the neck of the femur the limbs must first be considered as lying parallel. The injured limb is drawn down until it is equal in length to the uninjured limb. The sound limb is abducted to its limit and the injured limb is then abducted until the two angles made by the legs with the body are equal and until the length of the legs is absolutely equivalent. After inversion of the femur reduction is accomplished. It is frequently necessary to lift up the femur on the injured side because it drops backward away from the head. The muscles will not allow movement of the thigh. The patient is put in plaster. I saw very excellent examples of this at the Minneapolis General Hospital. No one can do it any better. Whether to use a double or single spica is for you to decide for yourself. The patient's wants can be taken care of, bed sores can be avoided by frequent turning in this rigid plaster and he is quite comfortable.

Factors that help an effort at bony union in the neck of the femur as in any bone are immobilization and rest, proper food and other physiological elements which include some irritation, but not weight bearing which will break down the maturing trabeculæ.

This slide shows a case of fracture of the neck of the femur which was rayed within a few minutes after the fracture. In the roentgenogram lies much of the interpretation of the fracture, and the exact requirements of the reduction, *i.e.,* what you want to do. The patient is put to sleep and the bone is put in position and you look forward to a reasonably happy outcome. You may or may not get a good result.

Six weeks later, while the patient is still in plaster, you should re-ray the fracture to study the decrease in density of the head as compared with the opposite head. Any X-ray shadow of the skeleton is dependent on the amount of calcium in the bone because the principal shadow-making material is the calcium salts. You study the head to see whether its density varies as compared to surrounding osseous structures. This film was taken six and one-half weeks after fracture and it looks as if the head is viable because, had it died, it would have become necrotic and it would retain the density as of the day it died and throw a shadow much darker, surrounding bone having lost calcium from atrophy of disuse.

Turning to the mechanical side of fracture in healing after the break is reduced and the head remains alive, the trabeculæ develop and after a given number of months, 6, 8, or 12, with judicious use, the trabeculæ finally line up and we have a head of equal density with the trochanteric portion. We then know we can depend on the union when the patient starts to walk.

This film is of a man 58 years old who fell down and broke the neck of his femur. Within an hour and a half after fracture I put him into plaster. This is six months later as it appears on X-ray examination. It looks to me as if the density of that head were very satisfactory. Here, one month later, the trabeculæ line up again. This is another month later, and the result looks very happy. Here it is four years later. The density of the head seems to me equivalent to the other; that head looks viable to all tests of the X-ray, and the patient is walking about and going to his business.

Some cases do not act that way. Probably the blood supply of the head remained in this instance but some of these fractures later unite and develop pain, lameness and possibly additional shortening. The causes of this are:

1. Insufficient period of immobilization.
2. Too early weight bearing, usually without the help of the caliper.

Other minor causes are:

1. Excessive body weight.
2. Condition of the vascular system.
3. Impaired myocardial action.
4. Poor nourishment.
5. Endocrine disturbances.

These fractures are not confined to older people, but fractures of the neck of the femur occur in children. These pictures are of a young boy with epiphyseal separation. This epiphysis was separated when the boy was wrestling with an older person and I made this reduction. It looks to me as if it were fairly satisfactory. He was kept in plaster sixteen weeks, and was then put in a caliper for four and one-half months. About a year and a half later he was sent away to military school and was subjected to serious over-training, over-walking, etc., as a part of the discipline to which he must conform. He came back in two years with a limp. I found when I came to X-ray it that there was an irregular shaped head and thickening angulation in the neck. He had pain. Immediately he was taken out of school and in spite of my best efforts this head went on to further destruction. Three months later, on X-ray examination of the head we found it was flattened, spread out, and light spots of bony replacement existed in it. Six months later, although he wore a caliper there is still some dark area in the head. No doubt that head is undergoing absorption and breaking up into fragments. Nine months later, in spite of wearing the caliper there is flattening, a change of configuration, and a little narrowing of the head portion. This is a graphic story of that case for four and a half years.

The next picture is taken eight years after the fracture through the epiphysis and we see that the neck is thickening; there is some new bone formation around the trochanter. The boy is in school but can't play football and can't engage in sports. There may still be dead unreplaced bone in that head. He had all the attention that the surgeon could give him.

It is difficult to get autopsy specimens of fracture of the neck of the femur and in twenty years' endeavor I have not had very many. This photograph is an impacted fracture of the neck of the femur occurring simultaneously with a fracture of the shaft. The shaft fracture has healed; it has abundant firm callus. The head of the femur, however, is not very firmly attached. The cartilage looks pretty good. On the whole, the head looks reasonably viable and yet after four and a half months the neck does not seem very well healed. On cutting through the specimen here is the healed shaft fracture; the medullary cavity is filled with callus. It looks well united. But the neck and head look different and there is no strong union, no rearrangement of the trabeculæ. We X-rayed that head, and in this picture we see the head with its density in the central portion largely that as of the day of injury. Here are some old trabeculæ; here is new bone formation, or at least invasion of bone. The main part of the head is dead; there doesn't seem to be a real bony union. The fracture plane is not thoroughly united; there is a lot of replaced bone, representing nearly a half or a third of the head. The fracture plane and head present an aseptic necrosis back from the fracture edge.

Another specimen recovered 6 and one-half to seven months after fracture, at which time the patient died, shows that the head has undergone some replacement; the cartilage does not show very distinctly. This replacement has not built itself into the firm trabeculæ that could stand wear and tear.

Shall a head showing areas of dead bone be removed or be used in a scheme of treatment which contemplates its complete final replacement and ossification? What I want to bring before you is a study of the bone that will help us in prognosis and treatment.

When we come to the treatment of ununited fractures we have to consider:

1. Direct treatment of the fracture, body plaster of Paris, after extension, inversion and abduction of the leg even if the head is dead.
2. Active treatment for
    a. Incipient ununited fracture.
    b. Established ununited fracture.
    c. Separation of fragments or true nonunion.

Our mainstay of help in these cases is the walking caliper, which is the best friend we have while waiting for these changes to go on.

Is there not something more in fractures of the neck of the femur than sheer mechanical apposition? Is there something more than reducing it under the Whitman maneuver? We must admit, however, that this method of treatment is perhaps the best yet devised, but we must prolong our investigation of the progress of these cases and there should be checking X-ray control during the course of encasement in plaster and after the patient is removed from the dressing. If ununited fracture with failure in trabecular alignment develops or the head shows evidence of aseptic death a prolonged freedom from weight bearing must be indicated. My purpose then is to stimulate you into further study of your fracture cases looking towards the betterment of treatment in general and of this particular type especially.

The banquet was well attended and there were many out-of-town guests.

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of January 13, 1932

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, January 13, 1932. Dinner was served at 7 o'clock, and the meeting was called to order by the President, Dr. J. S. Gilfillan at 8 o'clock. There were 57 members present.

Minutes of the December meeting were read and approved.

Annual reports of the Secretary-Treasurer were read and approved.

The Academy voted to offer, through the Board of Regents, an annual prize of $100.00 for the best piece of original research work of an undergraduate student of the University of Minnesota; the prize to be awarded by a committee selected by the Dean of the Medical Sciences, one member of which committee shall be a member of the Minnesota Academy of Medicine.

The President appointed a committee to draw up resolutions on the death of Dr. H. Longstreet Taylor, who died January 2, 1932.

Upon ballot, Dr. C. N. Hensel of St. Paul and Dr. F. H. K. Schaaf of Minneapolis were elected to Active membership in the Academy.

Dr. Gilfillan then called the President-elect, Dr. J. C. Litzenberg, of Minneapolis, to the chair.

Dr. Litzenberg: I would be ungrateful indeed if I did not seize this occasion to voice my grateful appreciation of the honor you have shown me by electing me President of this Academy. Honors may be real or not, as the occasions indicate, but when one is elected to preside over a society of the character of the Minnesota Academy of Medicine by his intimate colleagues who know his faults, it is an honor indeed.

I am now pleased to introduce to you the retiring President, Dr. Gilfillan, who will give his President's Address on "Compulsory Sickness Insurance."

Dr. J. S. Gilfillan (St. Paul) then read his Address, to appear in Minnesota Medicine at a later date.

DISCUSSION

Dr. E. L. Gardner (Minneapolis): Is it coming here?

Dr. Gilfillan: I think quite surely within not too long a time it is going to come up for consideration. Of course the United States is different from Europe. Very likely it will come up in the states. Social insurance has already gone quite a ways in the United States; we see that in various lodges, industrial plants, etc. All these social insurance instances are predecessors of compulsory insurance, but I think it will be a long time before it is universally applied in this country. It will come up for discussion at least, but whether or not it will be accepted I don't know. The American Dental Association has investigated this quite thoroughly; they have raised funds and sent representatives to Europe to study the various systems over there, and they are quite ready for it. The medical profession should get in on it so that they will have something to say about the framing of the laws and the administration of the scheme. In Germany it is probably more unsatisfactory than in any other country but of course Germany is very poor anyway and one can't apply that to the United States. I am quite sure that we will see the thing brought up and I think we should be prepared for it.

Dr. H. B. Zimmermann (St. Paul): In those countries in which the scheme is apparently quite satisfactory to the doctors, isn't that due entirely to their loyalty?

Dr. Gilfillan: It is due mostly to the organization, which has gotten in early enough. Another thing that helps a lot is the number of doctors. Norway, for instance, has one doctor to 1,900 population; so there it is easier to make it satisfactory than it would be in the United States where there is one doctor to every 750 of population. The total income per capita is less if there are two or three doctors to support in place of one.

Dr. C. B. Wright (Minneapolis): This is an exceedingly interesting and timely paper. I regret that Dr. Gilfillan did not have time to discuss the condition of the hospitals in these various countries. In Scotland, according to the best information I could get, the panel doctors are not permitted to do anything but the simplest emergency surgery. Cases needing operations and hospital care are sent to public hospitals. The staffs of these hospitals do the necessary work without compensation. In Sweden and Norway I have been told the hospitals are under the control of the state and the men are employed full time, in most cases receiving very small salaries. In fact at one time the medical association had to raise a large sum of money to support doctors who would refuse salaries below a certain point. In England the only income the surgeons get from private patients is where the patient is operated on in the surgeons' nursing home.

In this country, if the present method of building hospitals to give free hospital and medical care to veterans of all wars is continued, we will have much the same situation as far as hospitals are concerned. The Veterans' Administration has recently outlined a policy calling for the building of over 100,000 hospital beds in addition to the some 42,000 beds which they now control.

Dr. Gilfillan: In Sweden there is no compulsory insurance but there the medical society is pretty tight and also the number of doctors is quite low, about 1 to 2,800. Doctors are stronger when not too numerous. Sweden is under a voluntary system; but in Sweden the doctor himself cannot make a contract without the consent of the organization.

Dr. A. E. Wilcox (Minneapolis): You spoke of Lloyd George as being the man who put over the system in England, and the act becoming a law before the doctors knew anything about it. From what source did the plan originate?

Dr. Gilfillan: In the first place a lay committee was appointed. But Lloyd George was really the man who put it over with the representatives of the insurance companies. The insurance companies had the scheme all framed before the doctors knew anything about it.

Dr. R. E. Scammon (Minneapolis): It seems to me that the problem here presented is the one that we are always facing with regard to insurance and pensions. Everywhere we are trying to get too much for too small a contribution on the part of the insured. I once had occasion to take up an insurance plan with the President of a University and received a typical answer. He said, "There are two objections to your plan: first, it costs too much, and second, you are not providing large enough pensions." In practically all insurance plans we do not collect enough money and therefore we take it out of the profession; later somebody has to suffer.

I would like to emphasize also the point Dr. Gilfillan brought out about the number of practitioners, 750 individuals per practitioner in the United States. Last year I had occasion to figure out how fast practitioners were increasing. I discovered that they are increasing five times as fast as the population is growing, and that for every four men who were graduated from our institutions, one from a foreign institution is admitted to practice.

Dr. Litzenberg: In 1918, in my address as President of the Hennepin County Medical Society, I warned the medical profession that the socialization of medicine was surely coming and the degree to which it comes would depend upon the control of it by the medical profession, by studying the situation, and, as Dr. Gilfillan has indicated in his talk, by the profession taking control and have it governed by the profession and not have it forced upon us by lay agencies.

The meeting adjourned.

R. T. LaVake, M.D., *Secretary.*

PROCEEDINGS OF THE MINNESOTA SURGICAL SOCIETY

Meeting of October 23, 1931

The October meeting of the Minnesota Surgical Society was held in the Todd Memorial Amphitheater of the University Hospitals on Friday afternoon, October 23, 1931.

The meeting was called to order at 2:15 by Dr. Owen H. Wangensteen. The meeting was turned over to Dr. O. J. Campbell, who presided over the following scientific program:

"Tuberculous Empyema," a paper by Thomas J. Kinsella, M.D., F.A.C.S., and E. P. K. Fenger, M.D., Glen Lake Sanatorium, Oak Terrace, Minnesota, was presented by Dr. Kinsella.

Tuberculous empyema may develop in one of four general ways: (1) as a late development from a primary pleural effusion; (2) as a result of dense pleuritic involvement during or subsequent to a tuberculous pneumonia, oftentimes mistaken for a non-tuberculous empyema complicating pneumonia and treated accordingly; (3) as a complication during the course of artificial pneumothorax induced in the treatment of pulmonary tuberculosis; (4) from the spontaneous rupture of a tuberculous abscess or cavity into the pleural space either with or without a preceding pneumothorax. This latter type is almost always complicated by secondary infection. The first two of these are not seen frequently and are not usually recognized as tuberculous in origin, and are treated as non-tuberculous empyema, and a true diagnosis is not made until persistent draining sinuses call attention to a possible tuberculous background, or microscopic examination of tissue or guinea pig inoculation of the secretion eventually tells the true story.

In tuberculosis work, the type of tuberculous empyema most frequently encountered is that which develops during the course of artificial pneumothorax for treatment of pulmonary tuberculosis. Here, because of tuberculous involvement of an area on the visceral pleura, an effusion develops, usually clear at first with a low cell count, gradually or suddenly increasing in severity and amount until a purulent fluid is formed. The development of such a process may be gradual and silent, or sudden and stormy with fever, rapid pulse, chilliness, general malaise, etc., usually interpreted by the patient as an attack of grippe. Fluid soon appears in the pleural cavity discovered either by physical or fluoroscopic examination, or by the presence of splashing which the patient hears or feels. The purulent effusion represents a later stage or a more intense reaction of the same process which produces the clear pleural fluid. The fluid itself may vary all the way from a slightly cloudy or smoky fluid with a cell count of a few thousand to a very thick greenish or yellowish pus with cell count ranging from many thousand to several hundred thousand or more, depending upon the intensity of reaction and the time the fluid has remained in the pleural cavity. Tubercle bacilli may be easily demonstrated on smear in some fluids, while in others they can be found only with difficulty or by means of guinea pig inoculation. The patient, after the first reaction to the formation of the effusion, may have few or no symptoms aside from the weight and the splash of the fluid, but may feel toxic as long as pus is present.

Tuberculous empyema developing subsequent to spontaneous rupture of a tuberculous abscess or cavity into the free pleural space is almost always accompanied by sharp reaction, both from the sudden shock and embarrassment which follows the sudden collapse of the lung and from the marked inflammation which follows the massive contamination of the pleura with tubercle bacilli and secondary organisms. Fever, constitutional symptoms and prostration rapidly follow and the patient becomes very ill within a short time after its onset. The bronchial fistula may remain open, may close promptly, or may develop a check-valve action preventing the escape of air forced into the pleural cavity during paroxysms of cough, and by the positive pressure maintained greatly embarrass the patient mechanically by pressure upon the heart, mediastinum and diaphragm, or displacement of these structures.

In the treatment of tuberculous empyema without secondary infection or without artificial pneumothorax, three points are of prime importance: (1) evacuation of the pus; (2) obliteration of the pleural space; and (3) the avoidance of secondary infection. Open drainage by rib resection or catheter must never be used in this group of patients, for to do so will not only interfere with expansion of the lung and obliteration of the pleural cavity, but will allow the entrance of secondary infection, which must be avoided. Prolonged suppuration from any source is followed by degenerative changes of a lardaceous type in various organs. For this reason, we advise frequent removal of the purulent secretion from the pleural pocket through a needle and the washing of the pleural cavity with sterile saline, being careful always before withdrawing the needle to be certain that it contains no pus to contaminate the needle tract. A wide variety of antiseptics have been used but have gradually been discarded in favor of normal salt solution. If the lung is extensively collapsed at the time the empyema develops, it should be re-expanded so that it is at least half way out to the chest wall before it becomes bound down in order to facilitate subsequent obliteration of the pleural space. If the underlying disease in the lung itself has healed sufficiently to permit complete-expansion of the lung, then this should be done without delay for the final healing of a tuberculous empyema is dependent upon the complete obliteration of the pleural space. A few empyemas, after a period of aspiration with partial reexpansion of the lung, subside and do not recur. Others subside but recur at a later date, weeks or months later. If the patient's general condition and the disease process in the contralateral lung will permit and the lung cannot be expanded to meet the chest wall, the final solution to the difficulty is complete obliteration of the pleural space by extrapleural thoracoplasty, bringing the chest wall down to meet the partially expanded lung, with aspiration of all air and fluid. Complete obliteration of the pleural cavity can be proven by repeated physical and X-ray examination over a period of months or even years, supplemented by attempted aspiration of any suspicious area. Residual pockets, unrecognized, will eventually drain themselves as the tension increases either by perforation of the lung with drainage through a bronchus or by perforation of the chest wall. If, after maximum collapse has been obtained by a complete thoracoplasty, posterior plus anterolateral, an empyema pocket still remains, its roof should be totally removed, leaving no overhanging edges, and the pocket packed with gauze and allowed to heal by granulation.

Tuberculous empyema with secondary infection without bronchial fistulæ may be sterilized by the use of dyes, of Dakin's solution, or other antiseptics, and treated along the same lines as the uncomplicated tuberculous empyema. Tuberculous empyema with secondary infection with bronchial fistulæ is probably best treated by preliminary open drainage first, by catheter if the patient is desperately ill, later by rib resection placed as far laterally as possible so that it will not subsequently interfere with posterior thoracoplasty. With free drainage, sterilization is then attempted, being extremely careful to prevent entrance of any irritating antiseptic into the bronchial fistula. The lung is allowed to expand as much as it will. At a subsequent date, when the patient's general condition and the condition of the contralateral lung will permit, the pleural cavity is to be obliterated by a complete radical extrapleural thoracoplasty to be followed if necessary by an unroofing of any uncollapsed pocket.

DISCUSSION

Dr. O. H. Wangensteen (Minneapolis) felt that Dr. Kinsella had stressed very well effectual obliteration of the pleural cavity as an important element in achieving success in tuberculous empyema. But in general hospital practice perhaps the type of tuberculous empyema more frequently seen is that type in which there is no manifest evidence of tuberculosis present. Within recent months Dr. Wangensteen had observed two cases of this sort and he had been somewhat chagrined when he thought he had cured the patient of the pyogenic infection to find later on that the patient also had tuberculosis. The case histories of two such patients were related and the X-ray films were demonstrated.

The first patient was a girl of 20, in good nutrition, admitted to the University Hospital in 1931, with dyspnea and considerable fever. There was a draining sinus in the left chest and the patient gave the story that she had had an acute illness followed by empyema in September, 1929. Following the establishment of drainage at that time the patient improved very much and was quite well up to her recent illness. On admission here a catheter was passed into the sinus after slight dilatation of the latter with a hemostat. Irrigations with Dakin's solution were made and there was a complete subsidence of fever and dyspnea. An X-ray film of the chest at that time failed to show any evidence of parenchymal lesion in the lung. There was no sputum. Collapse of the rather large pleural cavity was undertaken by a combination of rib resection and decortication. Two such operative procedures were done before complete and satisfactory closure was obtained. Tissue excised from the pleura at operation showed giant cells and the pathologist suggested the diagnosis of tuberculous empyema. Later the guinea pig inoculation made from the pus aspirated from the sinus on admission of the patient was reported positive for tuberculosis. The patient has remained well.

The other patient, a boy of twenty-four, was admitted in June, 1931, with a history of severe sepsis of seven weeks' duration. His illness was sudden in onset and a diagnosis of a pyogenic empyema of the right pleural space had been made by his physician. A serous type of exudate with intermixture of large clumps of fibrin was obtained on aspiration. After drainage following rib resection, the course remained unaltered. The fever continued high, ranging between 102° and 103° F. daily with an occasional excursion as high as 104° F. and punctuated occasionally by chills. On July 10, another rib resection was done because of suspected pocketing of pus at a lower level in the thorax. The fever persisted unabated. The patient had continually complained of considerable pain in his chest and there had been marked tenderness along the incisions. The tenderness finally localized itself to the inferior portion of the scapula and though the X-ray films of the scapula exhibited no demonstrable lesion, it was believed that an osteomyelitis was present and the lower third was excised. The patient's condition immediately improved and a striking decline in the temperature to normal occurred. Pain ceased at once and the patient became ambulant and promptly gained weight. Tissue from the scapula removed at operation showed tuberculosis and the guinea pig inoculation with fluid obtained on admission was returned positive for tuberculosis. The patient has continued to do well and has been sent to a sanatorium for bed rest.

Dr. Wangensteen said that he would like to ask Dr. Kinsella if he sees cases of this sort and whether he has had similar surprises.

Dr. D. G. Gardiner (St. Paul) suggested taking out a piece of the pleura at operation.

Dr. Wangensteen stated that in the two cases just cited pieces of pleura had, of course, been removed at operation, but the evidence obtained appeared to be in total conflict with the clinical, roentgenologic, and operative findings in each case. In the instance of the first patient who had a pleural fistula and had worn a drainage tube, he had been inclined to believe that the histologic evidence could be correlated as well with a foreign body reaction.

Dr. J. F. Noble (St. Paul) said he wished to say that from a histologic standpoint it is not always easy to be sure from a biopsy that one is dealing with a tuberculous lesion unless tubercle bacilli can be stained in the tissue. Frequently foreign body reactions closely resemble tuberculosis and at times the inflammatory reaction is non-specific in character.

Dr. T. J. Kinsella (Oak Terrace) thought that the type of patient mentioned by Dr. Wangensteen represented an example of tuberculous empyema of Group I or II as mentioned in his paper. These patients usually present a picture of an acute non-tuberculous empyema and are treated as such until the chronicity of the disease, or the persistent draining sinuses, or the character of the discharge called one's attention to the possibility of a tuberculous process. He felt that it was pretty well proven that tuberculous empyema of this type develops secondary to a small lesion in the parenchyma of the lung or in the tracheobronchial lymph nodes and are not primary infections of the pleura itself, even though clinically the underlying lung lesion cannot be demonstrated. He stated that the clinical methods of determining small tuberculous foci were rather crude and that one may be greatly surprised when viewing the pleura through a thoracoscope, or at postmortem examination to note the extensive tuberculous involvement present, when clinically there was nothing to show for it except a small clear pleural effusion.

Dr. O. H. Wangensteen (Minneapolis) read a paper on "Chronic Occult Encapsulated Empyema." Two patients were shown, together with the X-ray films. The first was a man aged forty-eight who became ill in April, 1931, with pain in the lower right chest. Fever and cough followed and the patient soon began raising sputum in fairly large quantities. There was occasional blood-streaking of the sputum. He lost 20 pounds in weight and was unable to continue at his work. When admitted on the Medical Service at the University Hospital there was considerable sputum, often as much as 400 c.c. a day, with signs of consolidation in the lung. The latter findings gradually subsided but sputum continued in lesser amounts. The sputum was negative for tubercle bacilli but contained elastic fibers. Occasionally there would be very little and again considerable would be expectorated. The patient's condition improved somewhat but the fever continued between 100 and 102° F. and there was no gain in weight. The roentgen evidence of consolidation in the right chest gradually diminished but did not clear entirely. The patient also had syphilis with a positive Wassermann reaction and an aneurysm of the transverse arch of the aorta. After repeated aspirations of the chest a purulent exudate was obtained beneath the scapula posteriorly in which streptococci and pneumococci were identified. A lateral roentgenogram also demonstrated the residual shadow in the chest to be in the posterior portion of the chest. Pus was aspirated from the right main bronchus on bronchoscopic examination, but the findings were otherwise not conclusive as to the source of pulmonary suppuration. A diagnosis of encapsulated empyema was made and rib resection was done. As the pleura was cut down upon, it appeared quite normal. The pleura was then gently pushed away from the ribs and followed in the direction in which it appeared to increase in thickness. It was then incised and a surprisingly large quantity (a pint or more) of pus was obtained.

The patient has demonstrated considerable improvement and has regained his former weight. The wound in the chest has closed and the lung appears to have expanded. Sputum is still present and varies in amount from 30 to 50 to occasionally as much as 200 c.c. in twenty-four hours. A lipiodol filling of the bronchi shows a fairly well developed cylindrical bronchiectasis of the lower lobe bronchi on the right. The aneurysm displaces the right bronchus backward considerably and its lumen appears very much narrowed. A phrenicectomy will undoubtedly permit the diaphragm to rise somewhat and compress these dilated bronchi, despite the apparent fixation of the diaphragm by the previous empyema.*

The second patient was a man aged 36 who went through a severe pneumonia in January, 1930. He was in bed one month at the time and gradually got up and resumed his work after a few months. He lost 48 pounds in weight and did not appear to recover his former strength; a mild cough also persisted. Six months after his initial illness, his physician recovered pus on aspiration of the chest and a rib resection was done followed by prompt improvement. The wound closed and the patient continued at his work, never completely regaining his strength or weight. He continued to raise sputum in small amounts and periodically would cough up a good deal. Just before admission to the University Hospital the sputum had on several occasions been blood-tinged.

The patient ran a low grade fever and exhibited the physical finding of a thickened pleura over the right chest. Despite the fact that breath sounds were not audible over the lower right chest, the heart sounds could be distinctly heard there and more clearly than in the left axilla. The X-ray findings were those of thickened pleura with a suggestion of a small effusion. Examination of the sputum for tubercle bacilli and elastic tissue was negative. No exudate was obtained on aspiration. The findings here were so suggestive of encapsulated empyema that bronchoscopy was omitted. A diagnosis of encapsulated empyema with bronchial fistula was made and rib resection was done under local anesthesia on August 8, 1931. As in the previous case, normal pleura was at first cut down upon, but when followed in the direction of increasing thickness pus was immediately encountered upon incising the pleura. About 80 c.c. of fluid could be instilled into the cavity a few days after operation; it has gradually decreased in size, however, and the drainage tube in the chest has been withdrawn until it now only extends through the parietes of the chest wall. The patient states that he has regained his usual vigor and feels quite well.

These two patients, Dr. Wangensteen stated, represented not an uncommon type of case. The patient often presents himself for the treatment of pulmonary suppuration. The presence of the bronchial fistula in such cases aids in directing the attention of the physician to the chest but at the same time it gives rise to confusion of the existing empyema with lung abscess and bronchiectasis. Dr. Wangensteen felt that a careful evaluation of the history, the physical findings, the sputum and the roentgen films should lead to correct recognition of such cases in most instances.

In the second patient, the audition of the heart sounds over the right chest where breath sounds were inaudible was interesting. Fluid is a better conductor of sound than air and it is not unlikely that this may prove to be a fairly constant finding in pleural effusion and exudates of one sort or another. Heart sounds may often be heard over the lower abdomen in peritonitis in which a gaseous and fluid distension of the bowels together with the presence of a fluid medium between the coils of bowel serves as a good resonator for sound transmission.

An antero-posterior and a lateral film of the chest serve as the best indication for the location of the incision in the absence of a conclusive needling of the chest. Thickening of the pleura at operation suggests a proximity to the purulent encapsulation. Dr. Wangensteen urged operation and exploration of the chest in such cases to rid the patient of his continued pulmonary suppuration.

DISCUSSION

Dr. T. J. Kinsella stated that these cases of occult or localized empyema were interesting not only from the standpoint of diagnosis but also from the standpoint of treatment. They not only are frequently not diagnosed, but quite frequently misdiagnosed. He recalled one seen recently which had been diagnosed as lung tumor in which the early history was certainly indicative of empyema rather than of pulmonary malignancy. He mentioned another seen recently with typical history of pneumonia followed by empyema in which, because of a few unsuccessful attempts at aspiration, the diagnosis of empyema was discarded. When seen in consultation, two circumscribed pockets were localized by physical examination and pus obtained from both through an aspirating needle. The underlying principle in the treatment of this type of empyema is obliteration of the pleural space after evacuation of the pus by expansion of the lung to the chest wall if possible, because the lung itself is normal or relatively so in contra-distinction to many cases of tuberculous empyema in which the underlying lung is badly diseased with tuberculosis which demands a lung collapse and the obliteration of the pleural pocket by collapsing the chest wall down to meet the visceral pleura.

Dr. Wangensteen agreed with Dr. Gardiner that bronchoscopy was a valuable agent in the differential diagnosis of chest condition but stated that in suppurative lesions the findings were often indefinite and he was of the opinion that a careful interpretation of a well-taken history aided materially in getting properly orientated in such cases. Here were two patients, both of whom apparently had had pneumonia. The continued illness in either instance may have been due to lung abscess or empyema. In lung abscess there is usually considerable sputum continually; but if an encapsulated empyema with a bronchial fistula be present there is often a lot of sputum expectorated periodically with intervals during which only a little sputum is raised. With the ordinary criteria which everyone has at his command, these cases should be correctly recognized in most instances. The sputum of lung abscess usually exhibits elastic tissue; that of encapsulated empyema with bronchial fistula usually not. Both of these patients finally did well, but unnecessary suffering and considerable time could have been saved them, particularly with the last patient, by an earlier intervention.

Dr. Wangensteen stated with reference to Dr. Kinsella's remarks on carcinoma of the lung and sepsis that he too had seen several cases such as these in which the patient appeared to have a pulmonary suppuration. In one instance he operated upon a patient for lung abscess and the patient had twice previously been operated upon elsewhere with the idea in mind that he had pulmonary suppuration. Only shortly before the death of the patient was it even suspected that he might have a carcinoma of the lung. One common mode of manifestation of carcinoma of the lung, Dr. Wangensteen felt to be that of a pulmonary mass as visualized on X-ray examination accompanied by fever and chills. Sputum may or may not be present. The loss of weight is usually impressive and the patient often presents the appearance suggestive of malignancy. Within the last year he has seen three such cases, all of which were correctly diagnosed when first seen. However, Dr. Wangensteen said, one can take little pride in recognizing them when so little can be done for them.

---

*A phrenicectomy has been done, following which there was a material reduction in the expectoration.

Dr. Daniel H. Bessesen (Minneapolis) read a paper on "Certain Dangers From Spinal Anesthesia; thrombo-embolic disease, postoperative hemorrhage, sudden death, the exhausted or debilitated patient."

There are certain diseases or conditions occasionally referred to in the literature which cause peculiar dread and assume, in some cases, the proportions of the mysterious. These are thrombo-embolic disease, postoperative hemorrhage, sudden death and the effects of surgery upon the exhausted or debilitated patient. We have all had occasion to experience or draw conclusions concerning each of these complications, during or following the administrations of other anesthetics, but it may be well to consider them from the standpoint of spinal anesthesia.

Thrombo-embolic disease is one which at varied times causes death in from 0.1 to 0.5 per cent of all patients and occurs in all types of cases, most often appearing among otherwise healthy individuals, in clean as well as infected surgical cases, in all ages of life. It is possibly slightly more common among women, and favors patients with mild or long-standing infections. Giertz and Crafoord believe it to be essentially a surgical disease, finding a ratio of embolism between cases treated surgically and similar cases non-operated of 1 to 5.3. A. W. Meyer at the Charlottenburg Krankenhaus in Berlin, however, observed as many cases on the medical service as on the surgical. Bunzel reported 32 cases in 31,715 labors, though he reported it more frequently in operative deliveries than in spontaneous. So it may occur in surgical, obstetrical or medical patients.

There seem to be certain veins which are more susceptible to thrombo-embolism than others. Eighty-six per cent of all thrombi occur below the diaphragm, approximately 50 per cent in the left femoral vein. Other locations predisposed are the pelvic plexus of veins, the venous network of the dura mater, the auricles and prostatic vessels. Vessels in which the supine position causes a release of the overpressure observed in the upright position, produced by either blood or viscera, are especially predisposed. A widening of the vessel as in the auricles and in the veins at each valvular sinus, the possibility of a backward pulsation in the veins, the crossing of the left femoral vein by the inguinal ligament, the left hypogastric artery and the right common iliac artery are anatomic facts of importance in the etiology of the disease.

Aschoff places importance upon four possible factors, one or all of which may play a part in the production of the spontaneous thrombus changes in: (1) blood plasma; (2) blood elements; (3) the blood flow; (4) the vessel wall.

The mechanism of thrombus formation as gradually derived from the work of Virchow, V. Recklinghausen, Ferge, Aschoff, and others, seems to show that the platelets are deposited on the bed of the vessel as sand is piled on the bed of a stream in response to changes in its current such as whorls or eddies. Fibrin attaches to these hillocks. The leukocytes, being lighter than the red cells, drift to the margins of the stream and are caught in this network of platelets and fibrin and the process is repeated until the entire stream is blocked. The portion of blood between the obstruction and the next main channel then solidifies as a clot. This long clot when dislodged within the circulation may go to any part of the body and will find its embolic rest in accordance with its size.

A thrombus which is visible or palpable is usually of smaller caliber than one which is latent. Embolism from a manifest thrombus must be repeated to be fatal, while embolism from the latent thrombus is the fatal acute obstructive pulmonary embolism. The former is not subject to surgical removal; the latter has been removed nineteen times, with seven successes.

Waltman Walters has recommended thyroid substance together with early active movement as a preventive of thrombus formation. Essen-Moller used these methods in 300 surgical cases, with 300 controls, but notices no difference in ratio between the two series. Lately Rankin has reported that their observations at Rochester have likewise shown no lowering in percentage of thrombus formation since the institution of these methods.

Aschoff considers the variation in blood flow as the most important of the causative factors. Since spinal anesthesia has a faculty for temporarily lowering the arterial tension, it naturally follows that there might be some tendency on the part of this form of anesthesia to favor thrombus formation. Reports of this sort are not sufficiently frequent or numerous to know if there is an increase of this disease in cases where spinal anesthesia is used. There is probably no increase, since the disease is observed in all varieties of cases and under all types of treatment, and following the administration of all anesthetics.

A case occurred in my practice recently in which, for a pelvic repair, two injections of novocain were given into the spinal canal: the first of 150 mgm. novocain, for the perineal work; the second of 200 mgm. for the abdominal repair. These large doses were used because the patient was heavy. The operation was performed upon a Saturday; the patient died the following Wednesday from acute obstructive pulmonary embolism. The diagnosis of latent thrombus was evident from the fever, restlessness and gastric distress of the patient, combined with the sign described by Mahler, in which the pulse is more rapid than the temperature and respiration warrant. Death occurred in the presence of all members of the patient's family within fifteen minutes of the embolism.

Postoperative hemorrhage may occur in the presence of icterus, hemophilia, toxemias of various sorts. The mechanism which is attributed to spinal anesthesia is that the fall of pressure permits a vessel to be incised without exhibiting any large flow of blood. The failure to clamp and ligate this vessel which naturally follows, leads to oozing from that vessel when later the blood pressure increases. Rankin especially has emphasized this complication. Whether he has experienced this frequently or not I do not know, but Rankin is a strong exponent for spinal anesthesia. In my own practice I have observed postoperative hemorrhages apparently of this origin. The painful fact concerning postoperative hemorrhage is that if the bleeding is not stopped, death is certain. Unfortunately postoperative loss of blood often occurs in individuals who have been subject to severe surgical procedures and the manipulation necessary to stop bleeding may produce enough additional shock to end the patient's life. There can be no demonstration of surgical judgment in such a case, however, as the choice lies between a 100 per cent mortality and the possibility of life. Fortunately the loss of blood produced by this particular cause of postoperative hemorrhage is slow.

Sudden death is a condition I have not encountered. It must be a terribly shocking experience. The true facts concerning this tragedy are not definitely known. One may theorize about it, however. There may be the nerve shock of the lumbar puncture, the pressure of the brain into the spinal canal with compression of the medullary centers. There may be injection of novocain into the blood stream with its attendant reaction or one can visualize the possible spread of the anesthetic solution to the respiratory centers, though this possibility has never been clearly demonstrated. Also there remains the occasional drug idiosyncrasy which may explain sudden death. One wonders if W. W. Babcock has ever encountered this complication. With his vast experience with spinal anesthesia, it may be that some of his deaths or threatened deaths could fall under this classification, but you remember he says that if you cannot have an operating room force which is so equipped as to get fluid into the patient's veins within 20 seconds of the start of that patient's reaction, you should not use spinal anesthesia. In a recent collapse on the table which one of my patient's suffered (under gas anesthesia) it was five minutes before the needle conducting the fluid could be introduced into the vein. By that time, the blood clotted in the veins, no matter where the attempt was made for venoclysis. We were forced to depend upon a combination of stimulants—adrenalin, caffein, sodium benzoate, pituitrin, ephedrine, camphor, and coramine—combined with the head lowered posture, and fluid by rectum. Though the patient survived this reaction, the strain of the imminent death was terrific. If Babcock can secure intravenous fluid in 20 seconds this may explain the absence of sudden deaths in his last 18,000 to 20,000 cases. It may be strongly recommended that all hospitals adopt this method of dealing with emergency complications in the operating room.

Thrombo-embolic disease, postoperative hemorrhage, and sudden death are complications of infrequent nature. The consideration of the exhausted or debilitated patient, is, however, one which is less uncommon, and with which everyone is at some time forced to exercise his judgment in the selection of an anesthetic. This type of case is not a desirable risk under any form of anesthesia and should be most carefully watched under spinal anesthesia. The exhausted and debilitated patient will not tolerate even a temporary fall in blood pressure. About five weeks ago, I had a patient who presented the following record. After taking a nine hundred mile trip with one hour's sleep he presented an acute mass in the upper right abdomen, with vomiting of 24 hours' duration. He did not eat for another 24 hours' time, during which a diagnosis was established which called for a really severe surgical procedure. This was undertaken under spinal anesthesia and the operation was discontinued before completion because of the patient's bad condition. A second operation was required to finish the procedure, from which also he convalesced only after a terribly trying reaction of 24 hours' duration, and he might have had the same results under any other anesthesia than the one used. We have no controls on which to base an opinion, but one wonders sometimes if a surgical patient might be slightly more responsive under a different management, and so it is in this case. A long protracted prostatic illness and cases of hemorrhage are other types, concerning which extremely good judgment is required for the selection of the best anesthesia.

It is natural to analyze one's experiences with a newer form of procedure, and it seemed a suitable time to look through some records on unfortunate cases dealt with surgically under spinal anesthesia. The studies on thrombo-embolic disease, postoperative hemorrhage, sudden death and results of surgical procedures on exhausted and debilitated patients impress me with the fact that some judgment must be exercised in the selection of anesthesia for various patients, with the need for immediate fluid injection attendant upon emergency complications in the operating room, and with the unquestioned excellence of spinal anesthesia when these various possible contingencies are kept in mind.

DISCUSSION

Dr. R. J. Moe (Duluth) said he would like to mention another danger which they experienced, namely blood pressure of 180 or over. It had been their experience that such patients do not tolerate a decided drop in blood pressure. A drop from 200 to 120 is not tolerated as well as a drop from 120 to 60 or 70. This is accounted for by the fact that the high blood pressure has been accommodated for by the patient. Recently they had been more guarded in operating this type of patient than they had been in the past.

Dr. G. A. Williamson (St. Paul) asked how long Dr. Bessesen felt it was necessary to keep the patient in the Trendelenburg position.

Dr. C. J. Ehrenberg (Minneapolis) called attention to a report some months ago in Surgery, Gynecology and Obstetrics of some French neurologist who had been working on patients who had had spinal anesthesia. They reported a number of findings of paralysis in the lower extremities, the spinal anesthetics having been given ten or more years before. Their impression was that it was due to some injury from the anesthetic.

Dr. Bessesen stated that the length of time for the Trendelenburg position should be at least three hours, or between three and six hours, if the postoperative condition of the patient does not contra-indicate it. He thought the patient should not have a pillow the first twenty-four hours at least. Concerning nerve injury, he believed that novocain was not used so extensively nine or ten years ago but that stovain was used about that time and if he was not mistaken that had been known to produce nerve injury. He did not believe novocain has such a tendency to produce nerve injury.

Dr. Edward T. Evans (Minneapolis) read a paper on "Delayed Lesions Following Trauma of the Hip."

In 1914 Axhausen, in an article entitled "Bone Necrosis and Sequestrum Formation" stated that "mild inflammatory reactions, particularly when associated with embolic or thrombolic processes and due to low grade micro-organisms, may sometimes result in necrosis which is followed by simultaneous absorption of dead bone and incomplete, irregular replacement by new bone."

We now know that necrosis may result from a number of so-called aseptic causes, namely injuries, vascular disturbances, chemical action, and radium.

Much has been written on this subject in the past few years and Phemister of the University of Chicago has studied this problem so thoroughly that I take the liberty of calling "aseptic necrosis" of the head and neck of the femur following trauma, "Phemister's Disease."

For a clear understanding of his concept of aseptic necrosis, I would refer you to his paper read before the American Orthopedic Association in June, 1930, and published in the Journal of Bone and Joint Surgery in October of that year.

In presenting these cases I wish to stress only two points: (1) the dire necessity of appreciating fully the blood supply variables of the hip joint in the early handling of a case of hip injury, and (2) the necessity for careful supervision and follow-up in the functional restoration of the part, involving above all a knowledge of how bone heals and the influence of function upon that healing.

Quoting from Phemister's article, is the following:

"The fate of bone which undergoes aseptic necrosis as a result of circulatory disturbance varies considerably, according to the environment of the necrotic area. If the necrotic bone is attached to and directly continuous with living bone, there is ingrowth of vessels and of fibrous and osteogenic tissues from the living into the necrotic area. There is usually survival of unossified osteogenic elements about the periphery and ends of the area that has had its circulation interrupted. By the process of creeping substitution the old bone is gradually absorbed and replaced by new bone, so that in the course of months or occasionally years the necrotic area is more or less completely transformed into a living one. Whether the amount of new bone formed is as great as the amount of bone which died depends largely upon the extent of living bone with which it is in contact and the amount of osteogenic elements surviving about its periphery. When these are both extensive, there may be complete replacement of the dead bone by new bone; but when limited, bone absorption may be greatly in excess of bone formation, so that incomplete replacement results, with the formation of bone that is less dense than the original and that shows varying degrees of cavitation. Functional stimulation also plays an important role in the rate and degree of transformation. In general the greater the degree of function the greater the rate and degree of transformation into new bone. If the necrotic bone is largely or wholly intra-articular and extensively bordered by articular cartilage, the attachment to the surrounding soft parts will be markedly limited and chances for revascularization and transformation will be greatly reduced."

In fractured neck of the femur, "If bony union occurs, the head is gradually invaded by the ingrowth of tissue from the distal fragment and sometimes from the hypertrophied round ligament. The necrotic marrow is replaced by vascular connective tissue and eventually by bone marrow, but the necrotic bone is much more slowly absorbed and replaced by a variable amount of irregularly arranged living bone. The necrotic cartilage is slowly absorbed and replaced by fibrous tissue, fibrocartilage, and to some extent eventually by new hyaline cartilage. If too much weight is borne on the head before it has been transformed into new bone, its weight-bearing portion may collapse with a resultant deformity and poor functional result, but this may be averted by prolonged avoidance of weight-bearing. The functional stimulation which comes from motion of the limb without weight-bearing is sufficient to hasten transformation of the head."

Case 1.—On October 20, 1929, this patient, then twenty-nine years of age, dislocated his left hip in an automobile accident. Reduction was successful as shown in this plate. The hip was not fractured. The patient made a normal convalescence and walked in six weeks and for approximately eight months had no discomfort.

About six months prior to my seeing him in February, 1931, he began to have pain in the left hip which gradually increased until he sought relief by applying for examination at the United States Veterans Bureau.

This X-ray shows the condition, February 14, 1931. The first X-ray was sent for and unsuspected fracture ruled out. The patient was placed in a plaster spica with bed rest for eight weeks with complete relief of pain. This was followed by weight bearing in the spica for a time and then the caliper brace, which he still wears when ambulatory.

The X-rays of May, July and October, show the gradual restoration of bone under protected functional use. There is no pain, the patient is happy and though he may later require arthroplasty for mechanical reasons, it is believed there will then be good bone to utilize for the reconstruction of his hip.

Case 2.—These X-rays are those of a woman of fifty-four who sustained an intracapsular fracture of the neck of the femur in June, 1928. It was beautifully reduced by a very competent man, the recovery was rapid, and she returned to her home to carry on an active social life, including dancing and a prolonged European trip.

The convalescence was considered complete until last December when pain developed.

The X-rays show the progressive late necrosis occurring (December, May, September).

The patient is doomed to one of two courses: (1) prolonged protection from weight bearing combined with functional use as allowed in a caliper brace (this, she refuses); (2) surgical reconstruction.

Dr. Myron O. Henry (Minneapolis) read a paper on "Osteosynthesis in Intracapsular Fracture of the Hip of the Dog."

In this work, fifteen experiments were performed upon the right hips of adult dogs of unknown age. After careful preparation of the skin and etherization, the right hip was exposed by a muscle splitting incision, severing only the tendon of the quadratus femoris muscle. The ligamentum teres was severed in order to dislocate the hip. An intracapsular osteotomy was then performed.

Round nails made of rustless steel were used to peg on the free head from the proximal side, after the method of Hey Groves, in four experiments. These nails failed to hold in every case without external immobilization and the round nail was therefore discarded as a means of internal fixation.

A highly polished, rustless steel screw was then devised by the author, having coarse double-pitched threads and a slot at both ends. Such a screw was introduced through a drill hole the size of its core, made through the head and neck of the femur, entering at the fovea capitis and passing along the axis of the neck to bite well into or through the cortex on the lateral side of the trochanter.

Four animals were immobilized in plaster of Paris spica casts after such an osteosynthesis had been performed. All four died, three of pneumonia, and one presumably from distemper.

The modern trend seems to be away from prolonged immobilization in the treatment of fractures near joints. Early active motion is thought to stimulate healing by maintaining normal circulation and preventing atrophy of disuse.

In seven successful experiments, no external fixation was used, and the animals were usually found getting about with stable hips a few days after operation. A dog, having four legs, will not use a painful or unstable extremity at all. Motion pictures were made to record the stability and degree of function in the seven successful experiments.

Conclusions.—Hey Groves method of proximal osteosynthesis was performed in fifteen experiments on dogs whose epiphyseal lines were no longer discernible on X-ray.

Round nails were found inadequate for fixation of intracapsular fractures of the hip without external immobilization.

All animals immobilized in plaster of Paris spica casts died.

A rustless steel screw of special pattern secured satisfactory apposition of the fragments of intracapsular osteotomy of the neck of the femur and maintained adequate fixation of the fragments without external immobilization.

Such a screw is practically inert in bone.

Complete bony union with revivification of the head occurred within forty-nine days in the animals sacrificed for microscopic study.

The capital fragment, devoid of all soft parts, in intracapsular osteotomy of the neck of the femur of the dog, readily unites and revivifies under the proper physiological conditions essential to the healing process in bone.

Early, continuous, and accurate contact, with absolute fixation of the fractured surfaces, is of paramount importance in the healing of fractures in the presence of synovial fluid.

DISCUSSION

Dr. Bessesen asked if the screw penetrated the trochanter what would be the results of leaving the screw in place?

Dr. Henry said that that was the intention, that he had tried to have the screw project through but only in the white dog did it show. He had decided, if he felt justified in doing this on the human, that he would have the screw much longer. There would be no need to remove it, as it was rustless steel and produced no reaction. He thought it would be all right to leave it in place.

Dr. Williamson asked if there was any absorption of the head.

Dr. Henry said no, not in the successful cases of this series. The head was chiseled off smoothly and he thought a fractured hip would be easier to do, because the edges of the fracture line were irregular.

Dr. Bessesen asked if there was any necrosis of the head, free of soft parts.

Dr. Henry stated that these heads were necrotic bone, temporarily, which revivified. He had microscopic slides showing the head and neck forty-nine days after operation showing no evidence of the line of osteotomy. He said if there is sepsis the head dies. He felt that more experimental work probably should be done along this line before the procedure could be tried on the human.

Dr. C. J. Ehrenberg (Minneapolis) read a paper on "The Use of the Cautery in the Treatment of Diseases of the Cervix."

Casual inquiries at a number of private hospitals, and the University of Minnesota Hospital reveals that a considerable number of operations are being done on the cervix uteri under the diagnosis of cervicitis, endocervicitis, erosion, laceration of the cervix, and infection of the cervix. While the writer has no wish to recommend the exclusion of surgery in the treatment of these conditions, recent gynecological literature tends to show that the subject of surgery versus cauterization and its allied therapeutic agencies is gradually becoming less controversial, and that more and more the tendency is towards cauterization. So that the recommendation of this last named therapeutic agent is justified.

The high incidence of disease of the cervix uteri is obvious to one who practises among women. And, while time limitations preclude an extensive discourse, a brief mention of those conditions underlying most cervical pathology is necessary to evaluate the benefits of the recommended treatment.

The cervix uteri is an organ having structural, functional, and locational peculiarities, which predispose it to infections both acute and chronic. Acute infections are usually of two kinds, those secondary to parturition and those due to gonorrhea. These are treated as acute infections in any other location, namely supporting treatment to the natural processes of healing. The structure of the cervix, however, is such that acute infection usually terminates in a chronic condition which demands some type of further treatment for cure.

The results of chronic infection of the cervix uteri are classified into two groups: those having constitutional relationships, and those having local relationships. It is now an accepted fact that chronic cervicitis is a focus of infection along with the other common sites of focal infection. And the writer has reason to believe, from numerous observations, that an interrelationship exists between infected cervices and other foci of infection; the existence of one being dependent on the existence of the other. Any constitutional illness demanding elimination of foci of infection must include the removal of any infectious process from the cervix.

The local symptoms arising from the chronic infected cervix uteri are many; leukorrhea, back pain, and lower abdominal pain are those most common, the latter being often a consideration in the differential diagnosis of abdominal disease. Another of the sequelæ of cervical disease is sterility, this commonly being stated as the greatest single cause of the secondary type of this condition.

The foregoing presupposes that infection is the essential factor in the pathology of the cervix. And, excluding new growths, such is the case. Treatment then must satisfy a number of requirements: (1) the thorough elimination of the focus; (2) a result which does not interfere seriously with any further functional demands of the organ. Secondary factors essential for consideration are: (1) the ease with which the treatment can be applied according to the facilities at hand and the necessary dexterity of the operator; (2) the economic aspects such as the length of the period of disability, the hospital fee, and the physician's fees.

Until recently, the accepted form of treatment has been of two kinds. The first or medical, consists of topical application of some type of astringent or antiseptic solution, or both, in conjunction with a hydragogue tampon. This treatment ordinarily violates only the first of the above stated requirements. While it may suffice in some cases to ameliorate the condition and to cure in a few mild cases, it generally does not eliminate the infection thoroughly. The second kind of treatment, namely, the surgical, was evolved through the failure of the first. Numerous operations were designed to remove the gland-bearing area of the cervix which was sufficiently deep-seated so as to be impervious to local applications. This treatment usually violates the second of the requirements, namely function, and further requires all of the facilities for a major surgical procedure, a trained surgeon, and a period of confinement, which, to say the least, is uneconomical.

Cauterization of the cervix uteri, though popularized in the last few years, and though still in the period of exploration, is not entirely new. Dr. Robert Dickenson has used the method for about twenty-five years. Without tracing the historical progress, the perfection and development of electrical equipment, along with the exploitation by commercial institutions, has done much to popularize the cautery and the electrode knife.

The writer, having had little experience with the electrode knife and having derived much satisfaction from the use of the cautery, wishes to outline the simple technic. The time of the cauterization in relationship to the menstrual cycle is of some importance; the period for cauterization being confined to the days intervening between the fourth day post-menstruation and the tenth day preceding the expected menstrual period. Pregnancy is a definite contra-indication to cauterization although in a number of cases of cauterization of the cervix as a treatment for sterility, the second cauterization was done without apparent disturbance at a time post-dating the subsequent pregnancy. Acute cervical inflammation and any type of acute pelvic inflammation contra-indicates cauterization the same as surgery.

The procedure can usually be done in the office without the use of a general anesthetic. Where the lesion is widespread or in cases of previous surgical measures a light general anesthetic may be given. The patient is put in the dorsal position with the thighs well abducted. The cervix is well exposed through the Graves speculum, a tenaculum forceps or a hood being used if necessary. The vagina and cervical canal are cleansed and an anesthetic solution is applied to these regions. A number of cauterization speculi have been devised, but a second Graves speculum (Peterson's modification) inserted transversely is very satisfactory. The speculi serve to insulate the vaginal walls from the heat. The patients are warned about the sound and odor of the procedure. Cauterization is then done, care being taken to withdraw the cautery frequently, so that the radiated heat on the vaginal walls will not become too intense. Apprehensive patients may complain of some pain on applying the cautery to the cervix. Experience, and various types of lesion, such as laceration, eversion, erosion, and cystic conditions guide the operator in determining the area to be cauterized. Two models of the Post cautery are used, one the knife blade tip and the other the large blunt tip, the employment of one or the other being dependent on the type of lesion. Occasionally the external os is dilated previous to the use of the cautery for a lesion in the cervical canal.

Only occasionally is there an immediate reaction to this procedure and then only of a psychic nature, as fainting. Also occasionally the patient will complain of some lower abdominal discomfort for the remainder of the day.

Following cauterization, a leukorrhea, often of a profuse nature, appears and remains from ten to fourteen days. This is easily controlled by douches once or twice daily. From the seventh to the ninth day following the treatment there may be some vaginal bleeding which is due to the separation of the slough. On a number of occasions the menstrual period following the treatment has been complicated by a severe menorrhagia, but, since the avoidance of cauterization during the ten days preceding menstruation, this complication has not arisen.

Complete healing does not take place until about six weeks after the treatment.

Often the application of a single treatment does not suffice and it must be repeated once, twice, or even three times before the desired result is obtained, although invariably symptoms are much diminished following the first treatment.

The writer's confidence in cauterization is so complete that no operative procedure has been attempted for some years. As mentioned before, there have been a few occasions when cauterization has relieved what previous surgery did not. Cauterization is used commonly postpartum on the minimal lesions so often seen, but never before six weeks have passed. A number of patients cured of a cervicitis following one pregnancy have passed through a second and third pregnancy without further demonstrable pathology of the cervix.

DISCUSSION

Dr. Bessesen asked if the treatment is used in pregnancy, and, if so, are there any changes in the technic.

Dr. Ehrenberg stated that in pregnancy he felt that it was contra-indicated, although one case when he had cauterized the second time it was very apparently very early in pregnancy.

Dr. J. J. Swendson (St. Paul) asked if the procedure is known as coagulation or carbonization.

Dr. Ehrenberg replied that the process is one of carbonization.

Dr. Swendson said that he had been greatly interested in this work and wished to call attention to the danger of stenosis occasionally following cauterization of the cervix. He had seen cases with a resulting pyo-endocervicitis causing focal symptoms which subside when the cervical canal was dilated and drainage established. He called attention to differences of opinion held as to the preferable method of cauterization, stating that Dr. Heaney of Chicago had abandoned linear cauterization because of resulting hemorrhage at times, and was doing flat cauterization in all cases. He also noted that there was recent mention in the literature of the benefit following cauterization of infected cervices during pregnancy and stated that no complications of the procedure had been observed.

Dr. Ehrenberg said that, with the lesion limited almost entirely to the cervical os, such as laceration and eversion, one is not apt to burn the external os and get contractions. For this reason, Dr. Dick recommends the platinum wire cautery as this can be put inside the cervical canal and the cauterization done there. Dr. Ehrenberg said he took a Hegar dilator and dilated the external os before inserting the Post cautery inside the cervix. There is some evidence that cauterization of the cervix may produce an endometrial change. He had the experience of having a menorrhagia following cauterization of a cervix. For this reason cautery is not done during pregnancy as he would not care to take the chance of producing a miscarriage. Even if the miscarriage were not due to the cauterization, one would likely be blamed. Also, the cervix, during pregnancy, is subject to considerable variation of size and shape, and one would get a better idea of the normal if cauterization is not done during pregnancy.

Dr. Leo G. Rigler (Minneapolis) gave a lantern slide talk on "Benign Tumors of the Stomach."

ABSTRACT

The benign tumors of the stomach are far more common than has previously been supposed, comprising, in the author's experience, about ten per cent of all gastric neoplasms observed. The polypi are the most common variety. Clinical diagnosis is difficult and in many cases impossible.

Roentgen examination when carefully done will reveal these lesions in almost all cases. The technic is of great importance, the use of pressure and only a small amount of the barium mixture being the essential features. The presence of a sharply outlined, round, filling defect which is central in position, somewhat movable, and shows normal peristalsis and flexibility of the gastric walls about it, is diagnostic of a benign tumor.

Those polypi which are located in the antrum of the stomach and are pedunculated may prolapse through the pylorus into the duodenum. Acute pyloric obstruction may thus occur with striking symptoms which may be completely relieved spontaneously only to occur again at a later date. In these cases the defect may appear to be in the duodenal bulb. In one case the author was able to demonstrate by manipulation under the fluorescent screen this prolapse of a papilloma through the pylorus.

Occasionally a benign tumor may slough off producing severe hemorrhage, symptoms of acute ulceration, or other findings. No scar whatever may be left on the mucosa. In such a case the X-ray findings may not be substantiated at operation due to no fault of the examination. The author has seen two such cases in one of which the sloughed fragments of the tumor were found in the stomach without any evidence in the mucosa to indicate their origin. Not infrequently the polypoid type of tumor may not be palpable even after the abdomen is opened and it is necessary to open the stomach before they can be excluded.

Benign tumors, especially the adenomata, adenomyomata, papillomata, and fibromyomata, are frequently multiple and they may produce a sponge-like appearance in the gastriic roentgenogram—gastric polyposis. A similar appearance may be produced by a markedly hypertrophied or swollen mucous membrane without any real neoplastic tissue being present.

Recurrence of the tumors may take place after operation, although it is not common.

Malignant degeneration of these benign lesions is not uncommon and forms one of the indications for operation. It is possible that ten per cent of all gastric carcinomata arise in this way. In one case the roentgen examination revealed the typical picture of multiple benign polypi of the stomach. Nine months later, on the second examination, definite infiltration of the greater curvature with loss of peristalsis could be made out. At autopsy, benign and malignant tumors were found side by side.

Occasionally benign and malignant tumors may be demonstrated in the stomach at the same time, the two having no apparent connection.

Surgical removal of these benign neoplasms is indicated both to relieve symptoms and to prevent their degeneration into carcinoma.

DISCUSSION

Dr. J. F. Noble (St. Paul) stated that, for the purpose of general discussion, benign tumors of the stomach may be classified as adenomyomata, leiomyomata, and papillomata or polypi as they are generally called. Fibromata have been reported as occurring in the stomach but careful study has usually proven these tumors to be myomata. Lipomata have also been found in the stomach.

From a clinical standpoint, the adenomyomata are of relatively little importance. They are generally considered to be congenital in origin and arise from misplaced gastric or intestinal glands located in the muscle layer of the stomach. Their structure and origin are very similar to pancreatic and adrenal rests, which are also occasionally seen in the stomach wall. These tumors are, as a rule, accidental autopsy findings and are usually small.

Leiomyomata are also generally considered to be rather rare in the stomach but some recent work by

Rieniets, a Fellow in Surgery at the Mayo Clinic, has clearly shown them to be the commonest benign tumor of the stomach. Dr. Rieniets has kindly allowed the author to read his thesis, which is as yet unpublished, and to use some of his material in this discussion. In a study of 200 autopsy cases he found forty-three leiomyomata in thirty-two of the stomachs or in 16 per cent of the cases. Most of these tumors were small and of no clinical importance but his figures definitely show a surprising frequency for this type of tumor. Exclusive of this group he also studied all of the autopsy records at the Mayo Clinic for a six-year period and discovered only thirty-four tumors described, pointing to the fact that many of these tumors are overlooked in routine autopsies. He also included in his work twenty-one leiomyomata which had been removed surgically. From this series of cases he has brought out much interesting data.

He shows that the tumors may occur at any age, though they are much more commonly seen in older individuals. They are more common in males than in females. The tumors found at autopsy were commonly seen at the cardiac end of the stomach and those surgically removed were for the most part near the pylorus and at least four of them caused definite obstruction. These tumors may arise from either or both muscle layers of the stomach and may be intramural or pedunculated, the pedicles being attached either to the serosa or mucosa of the stomach. None of his tumors showed evidence of malignancy. Hausmann and others, however, have reported definite malignant smooth muscle tumors of the stomach. Rieniets also points out that these tumors may cause intussusception, mucosal ulceration and even perforations.

Next to leiomyomata, papillomata or polypi are the most common benign tumors of the stomach. They are of much more clinical interest because they are readily diagnosed by X-ray, as Dr. Rigler has shown, and because they are known to undergo malignant change. They are not uncommonly found accidentally at autopsy, either as single tumors or much more rarely as multiple tumors covering the greater portion of the gastric mucosa. Ewing describes this condition as gastritis polyposa. Multiple polyposus, however, is much more commonly seen in the large intestine. The tumors are pedunculated or sessile. They are papillomatous in structure, covered with fairly normal gastric mucosa and are supported by a connective tissue core carrying the blood vessels. Torsion followed by gangrene and complete disappearance of the tumors has been described by many writers and the writer believes that Dr. Rigler's case is best explained in this way. These tumors, because of their papillary structure, are also very prone to ulcerate and occasionally this ulcer causes severe hemorrhage as seen in another of Dr. Rigler's cases. From a clinical standpoint, however, the relationship of these tumors to gastric malignancy is their most important feature. From the work of Verse and others we can say quite definitely that most gastric carcinomas do not arise from polypi but rather from localized foci of malignant degeneration in previously normal gastric glands but occasionally they are responsible for clinical carcinomata of the stomach. Dr. Bell has observed two of these cases and other workers have followed these changes. It is common knowledge that malignancy frequently follows polypi of the rectum, bladder and other mucous surfaces. It would seem to be a good general rule to consider all papillomatous growths of mucous surfaces as potentially malignant tumors and to treat them accordingly.

Dr. Harold Leland (Minneapolis) read a paper on "Ascheim-Zondek Reaction."

Laboratory tests for pregnancy are at least 3,000 years old as evidenced from an Egyptian papyrus reading: "A woman may determine if she is pregnant by taking some earth and barley in a vessel and adding to it day by day a little of her urine. Should the barley grow, then she is pregnant, but if the grain does not grow, then she will not bear a child."

In 1928 two German investigators, Ascheim and Zondek, in the Klinische Wochenschrift, reported a more reliable and accurate test for pregnancy which bears their names. The principle was derived from the fact that when 10 mgms. of hypophysis were implanted into the muscle of the thigh of an infantile mouse, the animal went into estrus after four days. Normally a mouse weighing 12 gms. goes into estrus in the sixth weeks. The above experiment was done on mice three weeks old weighing about 6 grams. The estrual changes in the vaginal mucosa are not directly caused by the hypophyseal hormone given off from the implanted material, but indirectly by way of the ovary. The hypophyseal substance makes the infantile ovary mature, and this leads in turn to the changes in the vaginal epithelium.

Ascheim and Zondek in hundreds of experiments and thousands of serial sections have shown that there are three chief morphologic changes produced in the infantile ovary under influence of the hypophyseal hormone. The ovary of the immature mouse contains only primordial follicles and small graafian follicles without cavities. The first change caused is growth of the follicles, leading to rupture and discharge of ova into the tubes. Second, there occur hemorrhages in many of the enlarged follicles which are visible to the naked eye as cyanotic dots. Finally atretic corpora lutea are formed in the ovary by luteinization of the follicles which have not fully matured. The substance, which, in the implantation experiment makes the changes in the ovary, is present during pregnancy, as Ascheim has found, in the decidua, in the corpus luteum, in the placenta, in the amniotic fluid, in the young embryo, in the blood serum in large quantities and, most important, in the urine of the pregnant woman. This excretion of the hypophyseal hormone in the urine of the pregnant woman forms the basis of the Ascheim-Zondek test.

Technic: The first specimen in the morning is the best for use. Five mice are used each weighing from 6 to 7 grams. The injections are given with a tuberculin or insulin syringe into the back of the animal. Three injections are given the first day consisting of 0.2 c.c. for the first mouse, 0.25 c.c. for the second, 0.3 c.c. for the third and fourth and 0.4 c.c. for the fifth. Three similar injections are given the second day. One hundred hours later the animals are killed and the ovaries examined. When the test is positive, the ovaries are two to three times the normal size (which is the size of a pin head) and are red, presenting cyanotic protrusions due to hemorrhage into a follicle or a corpus luteum. If there is doubt about the ovaries, serial sections are made by fixing in Zenkers and embedding in paraffin. The microscopic finding of even one single corpus luteum renders the test positive.

But great difficulty exists in maintaining a colony of white mice 21 days old and weighing six to seven grams. So Friedman modified the above technic using young rabbits weighing not less than four pounds which had been carefully isolated in separate cages. It is known that the rabbit, although its ova continuously ripen, does not ovulate until after copulation. Thus it is possible to study the effect of the urine on ovaries free from corpora lutea and corpora hemorrhagica. From 7 to 15 c.c. of urine, usually 10 c.c., are injected into the marginal vein of the rabbit's ear. Thirty hours later the animals are examined. Positive tests are indicated by the presence of corpora lutea and corpora hemorrhagica, which are detected by gross inspection.

Results.—In 1,000 cases Ascheim and Zondek found the test positive in 98.6 per cent. In 470 controls they found no errors, and the cases of amenorrhea constituted the most important group. None of the 126 cases of amenorrhea gave a positive test. In one other test the physician had diagnosed pregnancy because of a missed period; the test was positive, but after a while the patient had some bleeding which probably was an early abortion. The reaction becomes negative about eight days after delivery but has been found positive on the ninth and on the twelfth day after abortion. It remains positive as long as living placental tissue is in biologic contact with maternal blood. Thus in tubal pregnancy one can expect a positive result only when the embryo is alive and not later than eight to ten days after its death. The results of 30 cases of tubal gestation were in conformity with the clinical and operative findings. The weakness of most tests for pregnancy is that other investigators do not obtain the same results, but the Ascheim-Zondek test has been used in 2,000 cases in the Frankfurt Clinic with 98 per cent accuracy, in Scheafer's Clinic at Charlottenburg in 100 cases with 98 per cent accuracy, in the Woman's Hospital of New York in 50 cases with one error. Using the Friedman modification, Reinhart and Scott reported results in 50 cases in which 49 were positive; Schneider reported 100 cases, 50 which were pregnant and 50 which were not. The results were exact in every case. Magath and Randall at the Mayo Clinic report 85 cases using the Friedman technic. Thirty-eight were pregnant and forty-seven were not. Their results also were exact in every case. In a personal series of sixteen cases, using the rabbit in four and mice in twelve, the results were all positive as checked by later clinical results. The rabbit is much the easier animal to obtain and use for laboratory purposes and most of the recent reports are with the rabbit as the test animal. Considerable work is being done using the male rat and Dr. Adair in Chicago reports excellent results with its use. The reaction consists of hypertrophy of the interstitial tissues of the testicle and of the seminal vesicles and the prostate.

Conclusions.—1. Pregnant women excrete large amounts of hypophyseal hormone in the urine.

2. Injections of urine from pregnant women into infantile mice leads to formation of corpora lutea and to hemorrhages in the ovary.

3. This reaction, the Ascheim-Zondek, is positive in 98 per cent of cases.

4. In tubal gestation and in abortion, the test is positive as long as living fetal tissue is in biologic contact with the maternal blood.

5. This test is also strongly positive in hydatiform mole and in chorionepithelioma, and in the latter is most valuable in determining treatment.

6. The writer makes a very earnest plea for the establishment of central stations where urines from pregnant women might be sent and the work done for a nominal fee, as is done in the British Isles, notably Scotland. The difficulties of obtaining laboratory animals and of technic are too great for the busy practitioner to cope with.

7. The test is a brilliant contribution to the field of diagnosis.

DISCUSSION

Dr. D. H. Bessesen said he happened to know that Dr. Leland had done all this work himself, and he felt the doctor should be complimented on the work. The analysis is these mice requires expert opinion but the rabbit is easier to work on. He felt it was splendid to have this laboratory procedure.

Dr. R. J. Moe (Duluth) stated that he had done twenty-five of these tests and he wished to call attention to the fact that there might be factors which would modify it. For instance, if one were testing a urine in which he might suspect the possibility of the presence of quinin, it is important to extract the quinin with ether. He had had one such case and so divided the urine into two parts and got a markedly positive reaction from the one without quinin in it and a negative reaction from the one with the quinin. There might be other things in urine, as acetone, which would modify the results of the test.

Dr. Leland replied that Dr. Moe's point is well taken. Zondek had the idea of a detoxifying agent, which is two to four times the amount of ether shaken with the urine. This reduced the mortality from 20 per cent in test animals to practically nil.

Dr. O. J. Campbell (Minneapolis) read a paper on "The Relation Between Cystic Disease and Cancer of the Breast."

The controversy over the relationship between cystic disease and cancer of the breast began with Billroth in 1880, when he wrote "Cancer does not originate in an otherwise normal breast." It has continued, so that even today opinion is for the most part divided into two groups.

One holds that cystic disease is definitely a pre-cancerous lesion and that the breast containing such a process should be removed to protect the patient against future cancer. The other group maintains that a breast in which cystic disease is present is no more likely to develop cancer than one which is entirely normal and, were it possible to diagnose the condition clinically, operation would not be necessary.

Two main lines of investigation have been followed by those who have contributed to these impressions: (1) microscopic study only, and (2) clinical follow-up of cases in which simple excision of part or all of the disease process has been done with preservation of the breast. Those following the first line almost always subscribe to the opinion that cystic disease is precancerous. Those following the second conclude that with certain exceptions cystic disease is not liable to malignant change.

Bloodgood followed 128 cases from which cystic disease had been excised or biopsied and found only three which developed cancer. Out of 107 such cases, Johnson found two cancers. In 1925, the writer followed cases operated at the University Hospital, in none of which had cancer subsequently developed. Since the incidence of carcinoma in these series was no greater than in normal breasts (about 2 per cent) the conclusion is almost inescapable that cystic disease is not a precancerous lesion.

Representing the other school of thought are such men as Ewing, Cheatle, McCarty, and Fitzwilliams, as well as older writers such as Brodie, Brissaud, Schimelbusch and others. Encountering in some forms of cystic disease a proliferation of atypical cells, mitotic figures, and even limited invasion, they interpret these as definite evidence of a malignant tendency on the part of the entire process and urge the removal of the breasts. Ewing finds pronounced pre-cancerous change in 50 per cent of cases of cystic disease examined by him.

Most of the confusion is caused by certain forms of the disease in which very marked epithelial proliferation has occurred. The best examples of this are the solid duct adenomas of Bloodgood, or the non-desquamative hyperplasia of Cheatle, intracystic papillomas and non-encapsulated cystadenomas.

These are the borderline cases over which pathologists disagree. Here the immediate question is not so much whether a precancerous condition exists but whether it is actually malignant at the time of the examination. That such lesions may give rise to malignancy is admitted by Bloodgood, who found that carcinoma developed in about ten per cent of papillomatous cysts and in even a higher percentage of non-encapsulated cystadenomas. Kilgore found carcinoma in four out of nine cases of non-encapsulated cystadenomas.

Where the diagnosis of cancer can be easily made in microscopic section it is interesting to note that the condition differs in no material way from other forms of carcinoma; that is, the clinical signs of malignancy are present and the axillary nodes are involved in a high percentage of cases by the time operation is performed.

On the other hand when the diagnosis is subject to disagreement it is noted that with rare exceptions the axillary nodes are free and recurrences do not follow, thus indicating that the lesions were either benign or at least of very low malignancy.

The surgeon placing the safety of his patient above all other considerations will be forced to do the complete operation on all doubtful lesions. Fortunately this group is small.

The evidence is strongly in favor of the view that except for the previously mentioned types in which epithelial hyperplasia so strongly dominates the picture, cystic disease is not a precancerous lesion.

Therefore, having established the diagnosis by exploration of the breast, the only danger encountered by the patient when the breast is preserved is that carcinoma, arising in a breast already the site of masses or nodules, may escape detection at its earliest and most favorable period. It would, however, be recognized when the clinical signs of malignancy are present. A rather remote danger is that, even removing the most suspicious area of a breast, an early carcinoma present in some other portion may be missed. These small compromises with safety seem justified in order to avoid the unnecessary removal of a large number of breasts. Where exploration reveals multiple intracystic papillomas or diffuse non-encapsulated cystadenomas, it may be wiser to remove the entire disease process even though it includes simple amputation of the breast.

Dr. A. A. Zierold (Minneapolis) read a paper on "Acute Cholecystitis" (to be published in full later).

ABSTRACT

Review of the literature discloses wide variance of the treatment of acute cholecystitis. This is chiefly the result of confusion of terms and absence of correlation between clinical and pathological findings. The term "acute cholecystitis" is commonly used to identify the gross appearance of the diseased gallbladder as characterized by edema, dark red hemorrhagic walls, with or without fibrinous exudate. Study of a series of sixty cases removed at operation tends to show that this condition is invariably accompanied by occlusion of the cystic duct with an impacted stone. As a result of this, obstruction of the veins and lymphatics occurs and acute edema follows. Inspection of the gallbladder wall, four to six hours after onset, reveals edema of the wall but no evidence of cellular invasion. Sections of the specimen removed twenty-four or thirty-six hours following onset show edema and round cell infiltration. This progresses to a maximum at seven to eight days, after which the process tends to recede. At the end of three or four weeks, the gallbladder returns to the condition at the time of onset, and shows no evidence of recent inflammation save some interstitial edema. At onset, the gallbladder content is sterile but as the condition progresses it may become infected and the return to normal be delayed. The term acute cholecystitis is commonly used to indicate a progressive change beginning with acute passive congestion of the gallbladder wall followed by leukocytic invasion and terminating in a return to the original state or hydrops of the gallbladder.

DISCUSSION

Dr. V. S. Counseller (Rochester) said these cases, which are extremely interesting ones, are difficult surgical problems from the onset. It is important to differentiate between the two types mentioned by Dr. Zierold because the dangers of perforation in the first group far exceed those of the second. Fortunately, the acute perforating gallbladder is seen less than the acute gallbladder following cystic duct obstruction. The management and course of the acute perforating gallbladder have been accurately and clearly set forth by Dr. Zierold. Dr. Counseller said he is more concerned at the moment with the acute gallbladder following stone in the cystic duct, for in many instances cholecystostomy is performed instead of cholecystectomy. He felt that cholecystectomy can always safely be done after the fever has subsided. It is his cystom to treat this group conservatively until the temperature has been normal for four or five days; cholecystectomy can then be performed safely. That cholecystectomy can be done safely is substantiated by the fact that all of these patients have an exceedingly normal convalescence. If one has diagnosed perforation of the gallbladder, it is best to establish drainage under local anesthesia with as little manipulation as possible; further treatment to be directed toward support of the patient. The principal point in Dr. Zierold's paper which Dr. Counseller wished to emphasize is that it is especially important to distinguish between the acute perforating type of gallbladder and the acute type following cystic duct obstruction because the surgical management and prognosis may be distinctly different.

Dr. Harold Leland (Minneapolis) read a paper on "Estimation of Disabilities for Industrial Purposes."

Recently there has been a definite step forward toward standardization of estimates of disabilities in industrial cases with several carefully planned schedules recently printed. There, of course, will probably always be differences of opinion as to the value of complete or partial loss of function of any given part of an extremity, at least until a more detailed standard is agreed upon by our Industrial Commissions. There is, however, no valid excuse for the large variations in estimates that are too frequently encountered. It is not necessary to dwell on the fallacy of pitching estimates low for purposes of effect in treated cases, or of making high estimates with the view of arriving at a compromise settlement. The purpose of this paper is therefore, not to particularly attempt to present any new schedule of rates or new methods but rather to explain certain fundamentals which might not be clear to all of us and which might guide our best judgment along uniform lines.

The Minnesota Compensation law describes a temporary disability and a permanent disability. Temporary disability refers to the time of healing following an accident and allows the man two-thirds of his weekly salary up to $20 a week, for a healing period of twenty-five weeks, after which his compensation comes out of his estimated permanent disability. The limit of such disability is 300 weeks. Occasionally where a man is partially disabled and not receiving full wages, two-thirds of the difference between his present and normal wages will be allowed.

Before going into the matter of permanent disabilities, let us consider for a moment the conditions which entitle a workman to receive temporary or permanent disability. In the first place, an accident has to occur which can plausibly account for the symptoms and disability present. On first consideration, this would seem to be simple, but remember that patients will frequently and conscientiously ascribe an illness or symptoms of a disease process to some accident or effort. Workingmen are becoming more and more educated to the fact that they have to have an accident in order to be entitled to compensation. Our most careful discretion must, therefore, be used in deriving the actual cause of an illness or disability upon which we can positively state whether or not a condition is due to disease or accident. Compensation insurance is not health insurance.

There are only certain designated occupational diseases which are compensable under the Minnesota Law. These are twenty-three in number, specifically described, and include such diseases as anthrax, lead poisoning and several similar chemical poisons; epitheliomatous cancer due to tar, pitch, etc.; glanders; compressed air illness and various conditions arising among miners, and cataract arising in glass blowers. It would be well to remember that aside from these specified diseases a disability has to have a specific accident as a causaive or aggravating factor to allow compensation.

In estimating permanent disabilities, it is necessary o understand that the Minnesota Law has placed cerain valuations in weeks of compensation on specified units of extremities and estimates have to be made accordingly. For example, a leg or an arm is valued at 200 weeks of compensation or, in other words, the oss of an arm or leg would entitle the individual to 200 weeks of his regular compensation after his healing period has terminated and regardless of whether or not he is working. The next smaller unit is the hand and wrist, which is valued at 175 weeks, or the foot and ankle, which is valued at 150 weeks. The hand alone is valued at 150 weeks, and the foot alone at 125 weeks. The value of the thumb is 60 weeks, the ndex finger 35 weeks, the middle 30 weeks, the ring 20 weeks and the small finger 15 weeks. The value of the great toe is 30 weeks, and each of the other toes 10 weeks. In estimating disability, therefore, we have to specify the percentage of the smallest unit involved. If an index finger is involved, the disability should be made as the percentage of permanent disability in this finger. If the metacarpal-phalangeal joint is involved, or any part of the hand not including the wrist, it should be made as permanent disability of the hand not including the wrist, and so on. No provisions are made under the Minnesota Law for estimating disability on the back. It should also be remembered that estimates under the Minnesota Law are made with regard to general usefulness without any relationship to any particular occupation. The basis of disability estimates should be the same, therefore, for all types of workmen.

In keeping with the purpose of this paper, the following schedule is not used with the purpose of giving a detailed schedule of disabilities for various types of loss of function in any one joint, but rather as a general guide to which one's judgment can be applied in any one case. The simpler the method of application, the better for the average individual inasmuch as the usual disability will be based on a combination of factors that in themselves might be complicated and confusing. The following schedule, therefore, is based on the loss of joint movements, so that we have an average normal value of any one joint. It is then comparatively simple to arrive at an approximate estimate by comparing the movement lost with the normal arc, the value of which we have established. The matter of ankylosis in a joint can be obtained fairly accurately from these figures, raising or lowering these figures according to whether the position is good or bad. The basis of comparison of normal function should be the opposite normal extremity and all angles should be accurately measured. For this purpose an ordinary carpenter's angle rule is sufficient. Also it has to be borne in mind that certain portions of the arc of motion are more valuable than others and that this might modify our estimates.

The value of the loss of joint movements is, therefore, approximately as follows. To avoid confusion, no attempt is made to give values of different types of ankylosis which are encountered comparatively infrequently.

UPPER EXTREMITIES

Shoulder movement	
Arm at side	75% of arm
From horiztontal to vertical	30% of arm
Elbow movement	
Good position otherwise	60% of arm
Pronation and Supination	
Neutral position	25% of hand and wrist
Wrist movement	
Dorsiflexion and palmar flexion, radial and ulnar deviation	35% of hand and wrist
Thumb	
Interphalangeal joint	50% of thumb
Metacarpal phalangeal joint	25% of hand
Fingers	
Proximal interphalangeal joint	60% of finger
Distal interphalangeal joint	40% of finger
Metacarpal phalangeal joint	Depends on finger and based on percentage of hand.

In testing movements of the fingers, we make it a rule if possible to hold the metacarpal phalangeal joint in a normal right angle flexion, which transmits the limitation to the interphalangeal joints and makes estimation easier.

LOWER EXTREMITIES

Hip joint movement	75% of leg
Knee joint movement	60% of leg
Ankle joint movement	35% of foot and ankle
Subastragaloid joint movement	35% of foot
Great toe, interphalangeal joint	25% of great toe

These figures frequently will have to be modified where other factors have to be taken into consideration, such as the involvement of multiple joints, associated amputations, nerve injuries, loss of strength, and the like. In the case of the lower extremities, particularly the knee, the loss of motion frequently is not as important as instability of the joint. Here, too, pain frequently has to be considered as, for example, in fractures of the os calcis. Shortening, which would play no material part in the upper extremity, would have to be considered in the lower extremity. A shortening of one inch would cause no disability; of one to two inches, 10% to 20% loss of the leg, and two to three inches, 20% to 35% loss of the leg.

Amputations have specified values according to law. The loss of one and a half phalanges or more in a finger or toe constitutes the complete loss of that finger, or toe. The amputation of the arm below the elbow constitutes the loss of the hand and wrist if enough of a stump is left to allow the use of an artificial limb. The loss of a leg so close to the hip that no artificial limb can be worn constitutes the total loss of the leg; if an artificial limb can be worn, 175 weeks is specified. Amputation below the knee with sufficient stump is valued at complete loss of the foot and ankle.

These facts are submitted with the knowledge that the figures quoted are subject to individual opinion and might justifiably be changed. Our purpose has been merely to outline a consideration of industrial disabilities which might be helpful to those who have not had the opportunity to familiarize themselves with the Minnesota Compensation Law.

The meeting adjourned.

D. G. Gardiner, M.D., *Secretary.*

McKESSON'S COPPER-IRON COMPOUND NOT ACCEPTABLE FOR N.N.R.

The Council on Pharmacy and Chemistry reports that McKesson's Copper-Iron Compound was presented as being of value in the treatment of anemia, with the statement that it contained copper caseinate 2.565 Gm., iron peptonate 5.700 Gm. in a menstruum of alcohol, glycerin, water and flavoring material to make 1,000 c.c. The Council examined the submitted evidence and found it insufficient to warrant recognition of a copper-iron preparation for widespread clinical use. Since McKesson and Robbins have not submitted acceptable evidence to show that its copper-iron preparation is superior to the iron preparations in current use, the Council declared it unacceptable for New and Nonofficial Remedies because of unwarranted therapeutic claims. (Jour. A. M. A., December 26, 1931, p. 1967.)

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

MEDICINE

THE DETOXIFICATION OF COCAINE, PICROTOXIN AND STRYCHNINE BY SODIUM AMYTAL: E. E. Swanson (Jour. Lab. and Clin. Med., 17:325, January, 1932). The purposes of this investigation are to ascertain definitely in experimental animals (rabbits): (a) Whether or not sodium amytal detoxifies the convulsant drugs which act on the parts of the central nervous system other than the cerebrum; (b) whether or not sodium amytal affords greater protection against poisoning by intravenous than by oral administration; and (c) the efficiency of sodium amytal in preventing the occurrence of convulsions inducted by these drugs. Picrotoxin and strychnine were selected for investigation, since the former is known to cause convulsions chiefly by the stimulation of the medulla, and the latter by that of the spinal cord. Cocaine, which is known to produce convulsions by its action on the cerebrum, was also studied under the same conditions for comparison.

The study revealed that sodium amytal detoxifies each of these three poisons. The detoxifying value of sodium amytal is greater when it is administered intravenously than orally. The difference between the two routes of administration is striking with cocaine and strychnine, but relatively less so with picrotoxin. When administered subcutaneously and intramuscularly with picrotoxin and strychnine the protective action of sodium amytal is even greater by vein or mouth. Subcutaneous and intramuscular injection of the drug, however, does not detoxify cocaine.

The administration of sodium amytal increases the dose of cocaine, strychnine, and picrotoxin required to cause convulsions, and also tends to lengthen the time required for convulsions to appear following the administration of these poisons. The intravenous administration of sodium amytal, being rapid in its effect, is of greatest value in cases of cocaine poisoning, since this drug produces convulsions very soon (three minutes) after administration. The oral administration of sodium amytal gave greater convulsant protection for picrotoxin and strychnine (poisons which produce convulsions twenty minutes after administration) apparently because of more prolonged and equal rate of the development of their effects. Sodium amytal, therefore, is an anticonvulsant as well as a detoxifying agent for these three poisons.

PEDIATRICS

EVAPORATED MILK IN INFANT FEEDING: Charles Gilmore Kerley, M.D., New York (Arch. of Ped., Vol. XLIX, No. 1, January, 1932): For the vomiting infant, for whom the thick feeding plan is employed, the author finds evaporated milk cooked with farina gives better results than when fresh milk is used; the satisfactory results of its use in the premature gives striking proof of its adaptability in subnormal infants.

During the process of evaporation certain changes take place in the milk which make it easier of assimilation. The finer division of the fat globules and a change in structure of the protein content by means of the homogenizing process doubtless explains in part this feature.

Regardless of the nature of the change, it has been clinically demonstrated that when given in connection with orange juice it supplies the most satisfactory substitute for human milk available at the present time in the routine difficult bottle feeding case.

For those that are ill from a digestive standpoint, in cases of maltnutrition and marasmus, those who vomit habitually and those with a tendency to looseness of the bowels, evaporated milk is employed, for the reason that it requires about 50 per cent less digestive effort than does fresh cow's milk. In food value one ounce represents a trifle over two ounces of fresh cow's milk. For purposes of better assimilation in some cases the starch is cooked with a designated quantity of milk and water for one-half hour in a double boiler; milk sugar is added after the completion of the cooking. The starch used is a baked flour of either barley, wheat or oats.

In the use of evaporated milk in athreptic babies, cod liver oil in small doses and orange juice are always given provided the child can take care of them. Neither are used if they influence unfavorably the food intake, appetite, or the nature of the stools.

Evaporated milk is always used to supply the milk content in thick gruel feedings. In these cases, in addition to the vomiting, there is always a lessened digestive capacity and the author has found that the child thrives best when the evaporated product is used. In beginning its use in the marantic child, it is rarely wise to use a stronger mixture than six ounces to 24 ounces of diluent. Clinically, 12 ounces of evaporated milk appears to possess the value of 30 ounces of fresh milk.

R. N. Andrews, M.D.

FIELD TREATMENTS OF ASCARIASIS, AN-YLOSTOMIASIS, AND TRICHURIASIS WITH IEXYLRESORCINOL: P. D. Lamson, H. W. Brown, . H. Robbins and C. B. Ward (Am. Jour. Hyg., XIII: 803-21, May, 1931). This study was prompted y the real need for a safe and effective ascaricide. fter trying out the various phenol derivatives, the uthors decided upon hexylresorcinol as the most ef-ective and least toxic. The drug was administered in ie crystalline form in hard gelatine capsules, a single ose of 1 gram being given orally upon a fasting stom-ch. The patient took the capsule upon rising and ontinued to fast until noon. A purge of magnesium ulphate was given after twenty-four hours. Experi-ients showed that hexylresorcinol in an oil solution, s caprokol, did not kill the ascarids; in water, it is nly slightly soluble, very unpalatable and irritating. 'he authors now report the results of field treatments n 1,500 individuals.

From 90 to 100 per cent of the worms were re-ioved by a single dose. The degree of success in the idividual case was largely dependent on the coöpera-on of the patient. Where the experiments could be erfectly controlled and the patient was starved for ighteen to twenty-four hours, 100 per cent cures were ossible, but where the children were allowed to eat iortly before the treatment, results were not so good nd there was some vomiting. This was attributed to ie fact that hexylresorcinol combines quite readily 'ith protein when present in the gastro-intestinal tract. xperiments with different amounts of the drug iowed that best results obtained with a dose of 1 ram for patients over twelve years, 0.6 to 0.8 gram to iildren from six to eight years and 0.4 gram to young-r ones. A repeated dose did not produce any better esults than a single one. Of those treated, 530 also ad hookworms, and these were reduced by 80 to 89 er cent; when a double dose of 0.6 grams each was sed, there were 88 per cent of cures. Some success in 'eating trichuris is also reported incidentally. The uthors are still seeking a method of putting up hexyl-esorcinol in stable form for clinical use, since the rystals react with gelatine after a while, thus ren-ering the drug unstable.

L. G. Frary, M.D.

GOLD TRIBROMIDE (AURUM TRIBROMI-UM) IN THE TREATMENT OF PERTUSSIS: . Epstein, M.D., New York (Arch. of Ped., Vol. LIX, No. 1, January, 1932): To witness a child dur-ig an attack of whooping cough is to be convinced of ie importance of some reliable drug which will alle-iate the spasmodic violence. Of all the drugs used or the relief of pertussis, the bromides give better esults than any of the other drugs. In observing the ction of the bromides in pertussis, the author was im-ressed with the fact that the bivalent bromides have reater sedative effect than the univalent bromides, and is therefore reasonable to assume that the trivalent romides would give greater sedative action than either f the others.

Gold tribromide was used by the author in a series f cases. Treatment consisted in the administration by iouth of a solution of the tribromide. The dosage aried with the age and weight of the child and the se-erity of the paroxysmal cough. As a general rule /20 to 1/10 of a grain, three times a day, was given. i very young children, 1/30 of a grain, three times a ay, was found sufficient to control the cough.

The result with gold tribromide in the 30 children 'as most gratifying. In two or three weeks the cough eased entirely. In the 15 children who received the sual antipertussis remedies, the cough was frequent nd racking, and the course of the disease was long, arying from three to four months.

Gold was used in medicine in remote ages. The medicinal effect of gold tribromide is probably due to a specific chemical combination of gold with bromine. The compound of gold tribromide inhibits motor and reflex irritability and causes a general sedative and antispasmodic action. For therapeutic purposes it is sufficient to know that gold tribromide shortens the period of the illness, reduces the number and severity of the paroxysms and gives the child rest and sleep.

R. N. Andrews, M.D.

ROENTGENOLOGY

TUBERCULOUS ATELECTATIC CIRRHOSIS OF THE LUNG—ITS ROENTGENOLOGIC SIGNIFICANCE: Karl Kornblum, M.D., and Richard T. Ellison, M.D. (The Amer. Jour. Roentg. and Rad. Ther., Vol. XXV, May, 1931, Pp. 620-628). In this article, the author calls attention to atelectatic cirrhosis of the lung as a lesion that may develop in the course of healing in tuberculosis.

He then reports two cases in which this lesion was the only manifestation of the disease and two other cases with the serial roentgenological findings showing the development of these lesions.

The underlying pathology is discussed. This begins with healing, the laying down of fibrous connective tissue. This tissue is deposited about the lesion and includes in it the bronchioles and bronchi. Then as healing progresses, there is a contraction of the fibrous tissue, which results in a choking of the bronchioles. This leaves an unaerated portion of the lung in the region of the lesion, and then the lung contracts and leaves a dense area, which in the roentgenological examination one finds in the lung field. If in the upper lobe, one may find the dense area and evidence that it is pulling the mediastinal contents and trachea towards it. This occurs when pleural adhesions are present. If there are no pleural adhesions present, the shifting does not occur but the space left by the contraction of the diseased area is filled in by emphysematous lung tissue. In this case, the hilus on the side affected is pulled up higher than the other hilus.

If the lesion is in the lower lobe, the diaphragm is elevated. If in the middle lobe, on the right side, there may be no change except emphysema. This condition has to be differentiated from such conditions as tumors of mediastinum, exudative and infiltrative lesions of lung parenchyma, such as unresolved pneumonia, or malignant growths, and atelectasis from complete bronchial obstruction by endobronchial lesion or foreign body. Physical examination is of little value in detecting it.

Sputum examination is commonly negative. Bronchoscopic examination may aid in the diagnosis.

Atelectatic cirrhosis is, the author thinks, more common than is realized, and may be the only evidence of tuberculosis. The disease may follow such a benign course that a history of illness is not obtained. It is always well for one to keep tuberculosis constantly in mind when making a diagnosis from X-ray films.

J. J. Rouse, M.D.

"INFRA-RED"

Under the incorrect and confusing name, "Infra-Red," the Iodine Products Co. of Caney, Kansas, describes an office test to determine the degree of acidosis. The designation, "Infra-Red," is applied to a "super-alkalized iodide." This test can do no more than determine the titratable acidity of the urine. However, this is not the method of choice in measuring the development of an acidosis. (Jour. A. M. A., January 2, 1932, p. 71.)

BOOK REVIEWS

COURTS AND DOCTORS: Lloyd Paul Stryker (formerly General Counsel for the New York State Medical Society). 236 pages, $2.00. New York: Macmillan, 1932.

This book presents in a concise and clear-cut manner the various aspects of the law as applied to medical practice. It is particularly valuable in laying down fundamental principles, both in avoiding and in defending law-suits, citing the best judicial opinion in defining the physician's rights. A particularly optimistic feature is the author's frequent proof that judges in their opinions are zealous in their efforts to help the physician so that he may practice, using his own best judgment, without fear of the intolerable bogey of unwarranted law-suits.

It is a valuable book and its reading will fortify the practitioner with clear-cut knowledge of his rights and his limitations.

C. H. Mattson, M.D.

RESEARCH COUNCIL BULLETIN 83.—STATUTE LAW OF CORONERS AND MEDICAL EXAMINERS IN THE UNITED STATES: George H. Weinmann, LL.B. 240 pages, $3.00. Washington: National Research Council, 1931.

As the title states, this bulletin is a compendium of the Statute Law of Coroners and Medical Examiners in this country. The mode of selection, qualifications and tenure of office of the Coroner are first considered; then the matter of deputy coroners. The powers and duties of the coroner in general, and most particularly as to inquests, are taken up in detail. Th statutes concerning compensation and fees are ther listed, and finally the laws relative to medical examiners (in the few states in which such officials exist) are recorded and discussed. The statutes of each stat and territory are listed, and leading cases are cited fo the questions of law considered.

No attempt is made to suggest reforms or to giv the relative value of the coroner and medical examine systems.

It is good as a reference book, and represents muc careful work.

Walter P. Gardner, M.D.

MEDICAL JURISPRUDENCE: Alfred W. Herzog Ph.B., A.M., M.D. 1,051 pages. Price, $15.0 Indianapolis: Bobbs-Merrill Co., 1931.

This is a well arranged and very inclusive work, intended for the use of both lawyer and physician. feel that the author is justified in his introductor statement that this book "will function as a guide boo to medico-legal knowledge."

The chapters are divided into sections replete wit references to footnotes, wherein ample and detaile references to cases are given, so that a thorough discussion of any point of law may be easily located.

A partial bibliography of pertinent medical works i appended to aid the lawyer, in securing more detaile information on medical subjects.

I feel that this is a book well worthy of a place i the libraries of lawyers and physicians.

Walter P. Gardner, M.D.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

FOR SALE—Office equipment including X-ray. Location in Minnesota town of 1,400 people. Average income of over $5,000 yearly for the past eight years. Unopposed. Specializing. Address D-150, care Minnesota Medicine.

WANTED—Affiliation with busy surgeon or practitioner in Minnesota. Ten years' surgery and general practice. Address D-165, care Minnesota Medicine.

POSITION WANTED—Registered nurse, five years' experience doing general office work, desires position in doctor's or dentist's office. Address D-169, care Minnesota Medicine.

EXPERIENCED X-RAY, LABORATORY, physiotherapy technician wants position in doctor's office, clinic, or hospital. Typing. Basal Metabolism. Anesthesia. Good reference. Address D-170, care Minnesota Medicine.

THREE GENERATIONS of experience in grindin specializing in fine surgical instruments. Prices, reasonable. Schwarz Grinding Service, Foot-Schul Bldg., 128 10th St. E., St. Paul. Telephone, Midwa 9939.

YOUNG LADY TECHNICIAN would like a positio in Clinic, Hospital, or Doctor's Office. Experience in X-ray, physiotherapy, and all clinical laborator procedures. Outside of Twin Cities preferred. References. Address D-167, care Minnesota Medicin

YOUNG LADY TECHNICIAN desires position i Clinic, Hospital, or Doctor's office. Experienced i X-ray, Physiotherapy, and all clinical laborator procedures. Also experienced in nursing and bookkeeping. Can furnish A-1 references. Address D 168, care Minnesota Medicine.

RELIABLE AND CAPABLE MEDICAL STENOGRAPHER-SECRETARY desires position. Can tak charge of office and also assist in treatment room Highest references furnished. Address D-171, ca Minnesota Medicine.

FOR SALE—To close estate: Completely equipp Minneapolis physician's office, including Fluoroscop X-ray, Stereoscopic Viewer, Metabolor. Phone number and same space is desired. Cash or reasonab terms. Howard P. Quealy, Administrator, 754 M Knight Building, Minneapolis.

COMPULSORY SICKNESS INSURANCE*

JAMES S. GILFILLAN, M.D.
Saint Paul

THE subject of compulsory sickness insurance has for a number of years attracted considerable attention, both in the medical profession and among the laity. Numerous articles on the subject have appeared in our journals and many lay magazines. The presidential address before the American Medical Association, in 1930, by Dr. Morgan, considers the subject quite thoroughly.

In 1917 the "American Association for Labor Legislation" caused to be introduced in legislatures of twenty-two of our states a bill which provided for the compulsory insurance of all employees. The state was to pay all administrative expenses, the balance to be divided equally between the employers and employees and the benefits were as follows:

1. A certain proportion of wages paid during disability.
2. Medical and hospital care, drugs, etc., for insured and family.
3. Expenses of rehabilitation.
4. Dental care.
5. Burial allowance.

These bills all failed to pass.

The great majority of these articles and discussions, however, are controversial in character, the writer or speaker considering the subject from his own point of view.

It appears that the subject is a live one and the medical profession should be informed on the subject. It may be that there is little probability of such a system being adopted in our country in the near future but it is, I think, sure to be proposed and seriously considered at some time. When this time comes the united profession should be ready to combat it if this should be thought wise, but especially to direct the legislation and gain as much influence as possible in the direction of the plan if it becomes inevitable.

In the present paper there is no argument for or against the system, but an attempt is made to show briefly its methods of application and, so far as possible, effect on the economic situation of the medical profession in some of the countries in which it is in operation.

First let us review a few statistics having to do with the general economic conditions as related to the cost of sickness in this country. The following table shows the estimated amount expended for this purpose.

150,000 physicians, at $3,000 per annum	$ 450,000,000
140,000 private duty nurses, at $1,500 per annum	210,000,000
150,000 practical nurses, at $1,000 per annum	150,000,000
100,000 attendants, at $1,000 per annum	100,000,000
50,000 dentists, at $3,000 per annum	150,000,000
7,000 hospitals, with total of 860,000 beds	750,000,000
Druggists, for medicines	700,000,000
25,000 healers, chiropractors, osteopaths, Christian Scientists, etc., at $2,000 per annum	50,000,000
Grand Total	$2,560,000,000

Of this amount about $800,000,000 is not paid directly by the recipients of the service but is contributed by government agencies, charity, etc.

For comparison the following national expenditures are given:

Jewelry	500 Million
Autos and parts	2 Billion
Candy	1 Billion
Perfumes and cosmetics	750 Million
Musical instruments	250 Million
Chewing gum	50 Million
Cigarettes	800 Million
Tobacco and snuff	800 Million
Cigar and cigarette holders	1 Million
Alcoholic beverages (Association Against Prohibition Amendment)	3 Billion

The total cost per individual then is about $21.00 or approximately $100.00 per family.

The average wage earner's family pays about

---

*President's Address before the Minnesota Academy of Medicine, January 13, 1932.

$60.00 a year, farmers about the same, for medical service. The total income of the United States is about $90,000,000,000.00. Incomes of families in 1927 were classified as follows:

6 per cent of families	over $2,900.00
90 per cent of families	under 2,000.00
67 per cent of families	under 1,450.00

The following shows the number of those employed in the care of the sick:

	Enumerations	Estimates
Physicians	143,000	
Attendants of physicians		24,000
Dentists	67,334	
Dental hygienists		1,800
Dentists' assistants		12,000
Dental technicians		10,000
Physiotherapists	500	
Osteopaths	7,602	
Naturopaths		500
Electrotherapists		300
Chiropractors		15,000
Christian Science practitioners	8,500	
Trained nurses		200,000
Practical nurses	151,996	
Midwives		55,000
Hospital superintendents (not included above)	2,600	
Hospital personnel (not included above)		550,000
Clinic attendants (not included above)		5,000
Optometrists and opticians	18,079	
Chiropodists and podiatrists		7,000
Masseurs		3,000
Pharmacists		100,000
Drug clerks and assistant registered pharmacists		84,000
Health department personnel (not included above)		11,500
Clinical laboratory personnel		1,400
Personnel of private health organizations (not included above)		1,000
Totals	399,611	1,081,500
Grand total		1,481,111

In the United States there is one physician to every 753 people, a higher proportion than in any other country.

The proportion in some of the European countries is as follows:

Switzerland	1 to 1,250
Denmark	1 to 1,430
England and Wales	1 to 1,490
Germany	1 to 1,560
France	1 to 1,690
Netherlands	1 to 1,820
Sweden	1 to 2,860

Distribution in the different states varies from one to 1,386 in North Dakota to one to 465 in California. The number of physicians employed full time on a salary basis is estimated to be 11 per cent. There are about 7,000 hospitals with a total of 853,000 beds. More than 50 per cent of these are supported by Government agencies and 25 per cent by non-profiting organizations.

Following the industrial revolution in the latter part of the 18th century and under the laissez faire economic system the condition of the working classes became desperate. The state made no attempt to alleviate their distress, trade unions were forbidden and employers were free to oppress their employees without interference on the part of the government.

About the middle of the 19th century some employers, prompted by their own interest or more humane motives, began to take an interest in the welfare of their employees and organized numerous institutions and funds for their relief. These efforts were unsatisfactory and opposed by the socialists on the ground that through them the laborer became more dependent.

Gradually laborers came to look upon themselves as a class opposed to the employers. More concerted action became possible, pressure could be brought on the authorities and the right to establish associations for mutual protection was obtained. So mutual aid societies and the friendly societies of England were established and spread over the continent, usually connected with trade unions.

This movement, however, remained limited and the organizations were apt to be weak financially, due to small membership, etc.

In time, the power of the labor vote being recognized, the authorities gave such societies a special status and even financial assistance. In consequence of this, societies multiplied and membership increased, but owing to multiplicity of organizations, small means, etc., were never entirely satisfactory.

A plan of compulsory sickness insurance was considered by the French convention in 1794 but never put in practice. Germany, in 1883, instituted the first compulsory sickness insurance system. This was apparently a political subterfuge on the part of Bismarck, directed against the socialist movement and the numerous trade funds which might be used in any disagreement with the State. For this reason it was opposed by the working classes. Since then the following countries have adopted this form of relief:

Austria and Hungary in	1888
Luxemburg	1901
Norway	1909
Serbia	1910
Great Britain	1911
Russia	1911
Roumania	1912
Bulgaria	1918

Portugal	1919
Czechoslovakia	1919
Poland	1920
Greece	1922
Japan	1922
Chile	1924
Lithuania	1925

France has just accepted the plan and Australia, South Africa and Brazil have the matter under consideration.

In the various countries now utilizing the system there are, of course, great differences in the scope, limitations, source of contributions, etc.

In the beginning, insurance was as a rule limited to wage earners in industry and commerce. As a rule it has gradually extended to include other employments, as agriculture, domestic service, home workers and, in some instances, to independent workers of limited means. It now includes the family of the worker in the majority of countries. In some countries the liability to insurance is confined to those whose income is below a certain amount; in others the income is not considered. Where there is a limit it usually applies only to non-manual workers. Thus in Austria, Czechoslovakia, Poland, and Russia there is no limit. The following table shows the limit in some of the countries in which it applies:

Country	Class of worker	Source of income	Maximum rate
Germany	Non-manual	Earned	3,600 marks ($900)
Great Britain and Northern Ireland	Non-manual	Earned	£250 ($1,250)
Hungary	Non-manual	Earned	24,000,000 crowns ($340)
Irish Free State	Non-manual	Earned	£250 ($1,250)
Japan	Non-manual	Earned	1,200 yen ($600)
Lithuania	All	Earned	4,800 litas ($480)
Luxemburg	Non-manual	Earned	10,000 francs
Norway	Non-manual	All	6,000 crowns ($1,600)

Once established, the tendency is to increase the scope of insurance. Beginning with wage earners whose income is below a certain maximum, this maximum is apt to be increased or done away with. The dependents usually are included and the medical care is extended to include hospitalization, specialists, dentists, sanatoria, more costly methods of treatment, etc. Usually special benefits are allowed to women for care before, during and after childbirth with often an addition in case the child is nursed. In addition, efforts are made towards the prevention of disease, especially tuberculosis and venereal diseases. Advice on housing conditions, etc., is often given. Ordinarily there is a cash benefit to partially cover loss of income during the illness. Often an allowance for funeral expenses is made.

When a law providing for compulsory insurance is adopted, some provision must be made for the management and application of the system. It is rare for the state itself to undertake this. At present only Bulgaria has a system in which this is done. Ordinarily the insurance is carried by societies which have been in existence previous to the passage of the act or which are later formed for this purpose. The government, however, must approve of the institution, which must conform to the provisions of the law regarding rates of contribution, benefits, etc. The state usually demands that the society does not do business for a profit, must have a minimum membership and reserve fund, and that the insured have a voice in the management. It must provide an opportunity for all to secure insurance. The societies are as a rule managed by the insured and employers, with, at times, representatives of the state.

The insurance group may be composed of those in the same occupation, as a trade union or all the employees of a business. It may be territorial, including all insured in a district, or it may be a mutual group of any kind. As a consequence there is much duplication of work and an unnecessarily high overhead expense. Some funds operate under more favorable conditions and are able to give extra benefits. Others are apt to be unstable as they are dependent on conditions in a certain trade or single undertaking. Many have too *small* a membership. There is a tendency for the number of funds to diminish through consolidation. At present Germany and Great Britain each have about 8,000 authorized funds.

In Poland, where after the war complete reorganization was necessary, territorial funds were established. Each covers an administrative district or large city and all insured residents of the district are compelled to join the same society. This is a much simpler plan than is usual and there are less than 200 organizations in the country.

The act which establishes the system specifies the source of the necessary contributions. These may be made by the insured, by the employers, by the state or by two or all of these.

In Russia the employer alone pays; in other countries the insured has to bear part of the expense; in Roumania all. In some of the Swiss cantons the cost is borne by the insured and the state, the employer not participating. Usually the insured and employers contribute about equally.

Individual share in contributions may be uniform, as in Great Britain. Here everyone pays the same, irrespective of risk or earnings. Usually the insured are graded according to their earnings, those receiving higher pay being assessed in proportion. Sometimes the assessment varies with the amount of risk.

The minimum benefit to which the insured is entitled is set by law. When an insurance fund is able, it may grant additional benefits.

The rate of money benefit may be the same for all, as in Great Britain, or may be graded according to the wages of the individual, as in most other countries. It usually amounts to 50 or 75 per cent of the wage, rarely to 100 per cent (*e.g.* Russia). In some instances the rate is greater for married men.

In order to claim benefits the insured must be unable to work on account of sickness. Usually the first three or four days are not covered by the insurance; thus brief illnesses are excluded. The duration of benefits varies in different countries from three months to a year. After this period the individual may be protected by an invalidity insurance, distinct from sickness insurance. If hospital treatment is provided, usually the cash benefit is reduced during the time the insured is in the hospital.

In addition to the cash benefit all countries except the Irish Free State provide medical care for the insured, which ordinarily includes drugs and curative appliances. In many countries hospital treatment is also given.

All laws specify that the medical treatment provided must be given by those legally qualified to attend the sick. Usually the insurance institution selects doctors according to some definite method. Treatment by specialists and dentists may be included or not. As a rule the patient is required to visit the doctor's office at certain hours, except when the nature of the case prevents. Drugs and appliances are provided under the majority of schemes, but every effort is made by the funds to keep down expense by supervision of prescribing. Hospital treatment is not compulsory but is given in many countries. Home nursing is usually not provided.

The organization of medical service is usually entrusted to the insurance organizations, with certain legal restrictions. In Great Britain, however, it is in the hands of the insurance committees, which are public bodies selected by the insured, the local doctors and the authorities. In some of the Baltic States the employer is responsible and in Russia the public health authorities.

There are three main systems of medical selection:

1. Any qualified doctor may apply for inclusion on the list. This application gives him the right to treat insured persons. The patient may choose any doctor on the list. There has been much controversy about this free choice, the medical profession usually favoring it, the societies often wishing to restrict it.

2. The number of doctors is limited according to the number of insured. Here the freedom of choice on the part of the patient is also limited.

3. The fund appoints one or more doctors in a locality, on full or part time, and the insured has no choice.

Doctors claim that a patient has a natural right to choose any doctor he wishes and that the society has no right to prevent this choice. The funds claim that an insured person has not this right, as he does not pay directly for the service, and for reasons of economy and simplicity prefer to do business with as few as possible.

Freedom of choice is also objected to on the ground that many persons will go to the physician who most readily grants disability claims.

Medical practitioners are not compelled to accept insurance patients. The organization of the service depends on contracts with the profession. In some countries the terms of the contract may be defined by law; in others the parties are allowed to come to any agreement they see fit.

At present in most countries the contract is made with a national medical society or some other body representing the doctors. Individual contracts are based on these. The situation of the medical profession usually depends on how well organized it is and how soon it unites on its demands after the institution of the system.

The remuneration of the medical profession is naturally one of the principal grounds of contention between the doctors and the funds or authorities. The method of remuneration varies and there are often several different methods in force in the same country.

1. A doctor may be paid a fixed salary. This is more usual when employed for full time but may be for part time.
2. Payment consists of a certain amount per insured person, irrespective of the amount of work done. The fee is based on the morbidity rate. This is the Panel System of Great Britain.
3. There is a fixed fee for each case of sickness, not depending on its severity or duration.
4. The fee is paid according to attendance. Usually a unit of attendance is chosen and for different services multiples of this unit are allowed. This is the plan usually favored by doctors.

In a few countries (*e.g.* Norway) the doctors do not accept a fee set by the funds. They make their own charge, which is ordinarily governed by a schedule agreed upon by the medical society. If this is greater than the amount allowed by the insurance society the patient is expected to pay the difference. This is not satisfactory to the insured and there are often difficulties in collecting.

It is rather difficult to estimate the effect of insurance on the medical profession. Nearly everywhere there is continual dissension between the doctors and the societies or government, but, so far as I am able to ascertain, in no country in which the system is in force is the profession in favor of giving it up. The complaints are rather directed against certain features of its administration.

The first item of contention is the amount received by the doctor for his services. Although in most, if not all, of the countries, the total income of the profession is greater than it was or would be without insurance, this cause of dissatisfaction is always present and probably never can be removed. Connected with this is the tendency to handle too many patients in a superficial way. Where the capitation fee is in force it is said that patients receive too little attention; where the payment is for work done, too much.

The freedom of the physician is, of course, restricted more or less. He must give notice of absences and provide a substitute and his prescribing is to some extent under supervision. At times there may be an investigation of his cases to determine whether his certification of disability is justified. The dissatisfaction of a patient may bring him before a lay body for trial.

A common complaint is the amount of work necessary on records, certificates, etc. This consumes much time and is usually not paid for aside from the regular fee. It is often said that doctors have become clerks and bookkeepers.

Where there is no free choice of a physician doctors are dissatisfied. Where there is free choice patients are apt to select the physician who is most ready to grant certificates.

Apparently there are many reasons for the dissatisfaction of the medical profession but it is difficult to see how any of them could be done away with entirely.

GERMANY

When compulsory sickness insurance was taken up by Germany there was but little voluntary insurance. The system was adopted without any precedent upon which to base it. The medical profession was not consulted and probably paid but little attention to the new order. Germany was at that time prosperous and doctors were independent. The scheme covered at first less than 10 per cent of the population, these being the poorer people who in any case could pay but little for medical care.

The government authorized the formation of funds. These were managed by the insured and employers, who contributed to their support. A fund might be established by a trade union, a fraternal organization, a factory or a department store. In addition there were territorial funds, each for a certain locality. All who did not belong to any other fund were automatically included in these local societies.

The state supervises and safeguards the funds. It specifies the maximum payment which can be charged and the minimum benefit to the insured.

Beyond this it interferes but little except in case of disputes between the interested parties.

Since the inauguration of the system numerous extensions of scope have been made. At present all industrial employees, regardless of pay, and others employed at a salary of less than 3,600 marks are covered by the plan. The law does not compel inclusion of the families of the members, but most of the funds now cover these also. In addition, voluntary insurance has become common and it has been estimated that at present between 80 and 90 per cent of the population is insured.

The societies are permitted to collect not more than 7.5 per cent of the wages of each worker. Of this two-thirds is paid by the insured and one-third by the employer. Funds are allowed to grant extra benefits if their finances permit. It will be seen that the contribution of the insured person depends on his pay, contrary to the plan in England. To simplify bookkeeping all liable to the contribution are divided into sixteen wage groups, according to their average pay.

The benefits are a cash payment of half the worker's wage. This begins on the third day of illness and continues for twenty-six weeks, and medical care for the same time. This care is quite complete, including hospitalization if necessary, dentistry, specialists, drugs, laboratory, X-ray and physical therapy. Ordinary appliances, as spectacles, trusses, braces, etc., are provided. Maternity and funeral allowances are included.

Recently, on account of the rapidly growing number applying for treatment for trivial complaints, the patient is compelled to obtain a permit at a cost of 50 pfennigs before seeing the doctor and to pay part of the cost of medicine.

Free choice of doctors from among those appointed by the funds is usually allowed. These are required to appoint one doctor for every 1,000 insured, or one to every 1,350 when families are included. The societies are trying to reduce the number of doctors while the medical men wish all to have right of treating insurance patients. A patient may change his doctor every three months, except when an illness which he is treating lasts over the quarter, in which case he must be retained for the duration of that illness. House visits are made only when the patient is unable to come to the office, and office visits must be made at a certain time. A patient may have consultation whenever he wishes.

At first the funds dealt with the doctors as individuals, but later the medical profession, through several organizations, has been able to bargain collectively with the insurance societies. All of the plans of payment for medical services mentioned previously have been tried and in different localities several are in force now. Perhaps the most general is the following: Instead of paying the doctor directly the funds pay to the doctors' union a fixed amount per quarter for each patient consulting a physician for any purpose during that period. Out of this sum the union pays the doctor, according to the work done by him. He is allowed one mark for an office consultation and two for a house visit. A surgeon is allowed 20 marks for an appendectomy, 40 for a stomach resection.

The union examines each doctor's records and if he seems to be charging unnecessary visits he is warned, fined or dismissed.

As insurance is so general, about 80 per cent of the doctors depend on the system for their living; about 15 per cent work for a salary; and only 5 per cent are able to get sufficient private practice to live.

The class of work done is probably not high, although perhaps the majority of the people receive better services than they would without insurance. In order to make a fair living a doctor must see from 50 to 200 patients a day. Some become very popular by granting disability certificates easily. It is said that few examinations are made. The fee is the same, so the less done the more remunerative the work is. The paper work necessary in handling patients adds very much to the work of the doctor and is a constant cause of complaint.

During the fifty years the system has been in force there has been a constant struggle between the doctors and the funds. This has been for the most part on the ground of fees, which have always been considered too low. However, there have been other controversial points, as the free choice of doctors, interference with treatment, limitation of the number of doctors appointed, etc. The plan has never been even approximately satisfactory to the medical profession. In 1923 the doctors refused to accept the schedule of fees offered and the funds established dispensaries with full time physicians in many places. The profession succeeded in having most of these discontinued.

A young physician has a hard time, as private practice is nearly out of the question and it may be necessary to wait for from three to five years before securing an insurance appointment. It is said that there are several thousand waiting at present.

The administration of the scheme is very complicated and expensive. There are nearly as many lay employees as doctors. The funds are powerful financially and politically. There are 70,000 secretaries of funds and Dr. Liek, in his book on social insurance, says that they are the masters of Germany's destiny.

The funds have in many places built fine office buildings, sanatoria, etc. The doctors complain that much of the money so used should be applied to the payment of better fees.

As in most countries, so here, the number of cases applying for benefits and the average duration of the case have been steadily increasing, this being probably due to the hard times. Efforts are being made to control this. The permit charge of 50 pfennigs was made for this purpose and has had some effect, but is objectionable as it often causes delay in calling a doctor when necessary. Late cases of appendicitis are common, perhaps as a consequence.

Control physicians are used to check up on claimants. In Braunschweig 2,008 patients were ordered to report for check-up. Of these, 816 reported for work at once and 289 were found fit for work by the control doctors.

It may be said that the scheme as applied is unsatisfactory to the medical profession and is perhaps not much better for the patients. The increase in irregular practitioners, who in some localities are said to make up 25 per cent of those treating the sick, has been attributed to the dissatisfaction of the workers with the services under insurance.

A reorganization of the whole system is at present under consideration. This contemplates centralizing the administration, raising the wage limit, extension to include classes of workers not insured at present and to have all claimants under the observation of control physicians. In spite of the unsatisfactory condition it is doubtful if many in or out of the medical profession would consider abolishing it.

ENGLAND

In England, before the passage of the National Insurance Act in 1911, voluntary sickness insurance was common among the working classes. In 1904, 5,700,000 were covered by the friendly societies.

These societies have certain advantages over those under a compulsory scheme, in that the members feel some interest in one another and some loyalty to the organization. It was usually a point of honor not to apply for help more than was necessary. Morbidity statistics taken from voluntary society experience have always resulted in a deficit when applied in compulsory insurance. Membership of these clubs was usually from the more thrifty workers, those most apt to become public charges ordinarily not joining.

Doctors contracted for the care of members on a per capita basis, usually 3 to 4 s. annually. A doctor might start a club of his own on the same basis. The pay was inadequate, the services not of a high order and there was much dissatisfaction among the members of the profession.

The National Insurance Act of 1911 covered sickness and unemployment. The Act is said to have been "hastily prepared, imperfectly considered and inadequately discussed." The methods of politics rather than those of science were employed. There were powerful corporations whose compliance was necessary for the passage of the act and these had to be placated by being given control of its administration. The doctors saw the danger but were susceptible to financial promises and too often the rate of payment stood before efficiency of service. Lloyd George originally intended the treatment of the insured by salaried physicians.

It would be interesting to describe in detail the fight put up by the British Medical Association in the interest of the profession when the act was under consideration. Lloyd George did not consult with the medical profession until he and the insurance companies had laid down the main lines of the scheme. For some years before this time the British Medical Association had been engaged in a campaign to secure better conditions under the voluntary plan, but not much progress had been made when the Act was passed. The association had no precedents to guide them and no experience in fighting the government. In spite of this they waged a fierce and, to an extent, successful battle, which by the way cost them a large sum of money.

The demands of the medical profession were summed up in what were known as the Cardinal Points, as follows:

1. The income limit for compulsory insurance was to be £2 per week.
2. There must be free choice of doctors.
3. The medical benefits were to be administered by local insurance committees, not by the funds.
4. The method of remuneration of physicians adopted by the committee must be that preferred by the majority of doctors in the district.
5. The remuneration must be considered adequate.
6. There must be adequate medical representation on the various bodies administering the insurance.

As to their success in the fight, it may be said that they did well but might have done better. Returning to the Points.

As to Point 1, the income limit, they failed. The objection on the part of the government was the difficulty in administering the plan. Among wage earners pay and employment vary and many would be in and out repeatedly.

Points 2, 3 and 4 were gained.

Point 5. The remuneration has always been considered inadequate by the doctors. This would probably be so in any case.

Point 6. The profession has never considered their representation altogether adequate.

The Act, passed in 1911, went into force in 1913. Up to the last the profession refused offers made them. Then a "rot" set in—some doctors were suspicious of others, fearing the work might go to others; there was a good deal of purely political feeling and fear of opposing the government. At the last minute the authorities announced that 10,000 physicians had offered their services and the fight was over.

In addition to their partial success on their Points, some substantial advantages were gained. The fight of the association and the sympathy aroused in and outside of parliament have made it impossible for the government in the future to act in any similar matter without consultation with the British Medical Association. It never since has denied the right of the doctors to consideration. The Insurance Acts Committee of the Association now meets with representatives of the Ministry on the framing or alteration of any regulations. While they do not always succeed in obtaining what they desire, a fairly satisfactory compromise is usually reached.

The Act applies to all persons between 16 and 65 years of age who are employed in manual labor and to all other employed persons whose remuneration is not over £250 a year. After 65 the old age pension is effective. Many are not included because not employed for wages.

These provisions bring under the plan about 15,000,000 persons or about 35 per cent of the total population, 78 per cent of the occupied, 86 per cent of the employed population.

The state contributes two-ninths of the cost of insurance; the balance is divided equally between the insured and employers. This amounts to 4½ d. a week for each.

The administration of the plan is in the hands of the Ministry of Health, the approved Societies and the Insurance Committees. The approved societies are those which previous to the Act had been writing voluntary insurance and many new ones since organized. The insured are supposed to have a voice in the management but often this is quite vague, as that of a small stockholder in a large corporation. The Societies, as usual, have great financial and political power.

The Act created about 200 Insurance Committees in England, Scotland and Wales. These are made up of representatives of the local council, insured persons, Ministry of Health and panel doctors. There is a committee for each county or county borough in the country. The committees were demanded by the medical profession to escape control by the societies. This committee keeps lists of doctors and druggists who have agreed to undertake insurance work, and also lists of insured arranged as to membership in a society and as to the doctor selected by them. It furnishes each doctor with a list of patients who have selected him. It also oversees the prescribing and the accounts of pharmacists.

Under the Insurance Committee are sub-committees to consider complaints of patients or doctors and matters of a professional character, such as over-prescribing. There is an allocation committee to see that all insured have a doctor, in case they have made no choice or a doctor dies.

The amount collected from the insured in the whole country is pooled and distributed by the

Ministry of Health to the Committee of each district according to the number of insured in each district. The amount assigned divided by the number of insured sets the capitation fee received by the doctors. This varies somewhat but recently has been 9 s. per annum.

In England all insured pay the same amount and are entitled to the same benefit, except a slight difference between men and women. A society may grant additional benefits and this is often done.

The legal benefits are: A cash payment of 15 s. a week for men and 12 s. for women while disabled by sickness, beginning on the fourth day and continuing for twenty-six weeks, after which a disablement allowance of 7 s. 6 d. a week is allowed until recovery or until entitled to old age pension. A maternity benefit of £2 for an insured woman or the wife of an insured man is allowed.

Medical treatment to the insured only.—This treatment is such as a general practitioner is able to give. The services of specialists are not included. In case of doubt as to whether a certain treatment is such as can be expected, the case may be referred to the medical committee. Numerous decisions and rulings already exist. For example, curetting the uterus and setting a fracture of the leg are obligatory; intravenous injections and general anesthetic for tonsillectomy are not.

Obstetrical care and treatment for ten days after labor is not included.

There are no provisions for consultations, laboratory or X-ray work, for nursing, hospital treatment, etc. Drugs are provided.

Every registered physician has a right to have his name placed on the list of insurance doctors. His success depends on his ability to secure patients.

Over two-thirds of the doctors and five-sixths of general practitioners in England are engaged in insurance practice. The average number of patients per doctor is 1,000. No doctor may have more than 2,500 on his list. Under the present capitation fee each doctor receives 9 s. per annum for each insured person on his list, whether sick or well. In addition to the regular fee mileage is allowed for any distance over two miles. The average panel of 1,000 gives a gross income of £450 or $2,250.00. It is estimated that as a rule the doctor receives about as much for treating members of the insured's family. A doctor may sell his list to any registered physician, usually receiving from 9 to 13 s. per capita. A list of 1,000 persons means on the average, for 300 days a year, ten office visits and four house calls.

The insured person has free choice of doctor among those listed. At first he could not change doctors without considerable delay. This rule was given up on the demand of the medical profession but has recently been put into effect again in an attempt to curb the increasing claims of disability. At present a change can be made only at the end of a quarter and with a month's notice.

The income of the profession has been considerably increased by the system. It is said that doctors not in insurance work have been able to increase fees because of the general increase in income.

The work of the doctor has been much increased. Records must be kept, reports made and certificates issued. The doctors complain of this, and it possibly might be simplified, but much of this work is necessary under any such scheme.

In regard to certification of disability the position of the doctor is a difficult one. In England, as everywhere, claims have been increasing rapidly. This increase was in the six years to 1927 from 60 to 100 per cent. This seems to be due largely to a change in the attitude, a lowered morale among the insured. It seems that they are out for all they can get. When impediments to a change of doctor were removed a powerful weapon was put into the hands of the insured. A doctor who refused to issue certificates, when asked, lost his patients. It is said that 99 per cent of changes of doctor were because of refusal to certify disability rather than dissatisfaction with treatment.

The Ministry of Health appoints Regional Medical Officers who examine cases referred by an approved society or panel physician. In 1927 of 210,000 referred for examination nearly one-half failed to appear and only 50,000 were found incapable of work.

The amount allowed for medicines is limited. If any doctor's prescriptions exceed the average they are investigated by a committee and if found more expensive than necessary the excess may be deducted from his pay. There is a tendency to over-prescribe, as the patients demand medicine. The amount paid for drugs is about one-third of that paid doctors.

On account of the increased claims the Ministry has warned the societies that they might have to reduce benefits. They are urged to investigate in order to determine whether certificates should be accepted. Doctors have been warned to exercise more care in granting certificates.

Recently it has been proposed to reduce the capitation fee by 10 per cent. So far the doctors have refused to accept this.

On the whole the system has been fairly satisfactory. In 1922 the British Medical Association passed a resolution stating that it was sufficiently successful to warrant continuance. There is still considerable opposition on the part of members of the profession but the majority favor it. According to the Association large numbers received medical service who formerly were without it, the treatment is better than under the old clubs and is applied for earlier. There is some interest taken in prevention, clinical records are being accumulated which may be of value and there is more coöperation and feeling of responsibility among physicians. There is still much superficial work done.

There is need for more extensive service, especially the inclusion of hospital care, specialists, laboratory work and nursing. At present from 50 to 60 per cent of patients applying for treatment in free dispensaries are insured persons, showing that they are not entirely satisfied with the service. This may be partly due to the lack of specialists.

Among the changes in the system which have been recently proposed is the inclusion of the families of the insured in the plan. Probably this would decrease the income of the doctor as the pay would be apt to be less than he receives treating them as private patients. Reduction of the number of patients on a doctor's list also has been considered. To this the doctors would agree providing the capitation fee were raised. A raise in the income limit has also been suggested, and the companies would like to employ salaried physicians. This is strenuously objected to by the profession.

NORWAY

Here the application of the system differs in several particulars from that in Germany and England. Here insurance was established in 1911. It covers the family of the insured. Manual workers are all insured. Non-manual wage earners were included if their annual salary was below 6,000 kronen, but this limit has recently been lowered to 5,200 kronen. This lowering of the salary limit is unusual, the tendency being to raise it.

The number of insurance organizations is limited and only one may do business in a locality.

The insured is allowed a certain amount for medical services, for instance in Oslo, 3.50 kronen for an office consultation and 5 kronen for a house visit. The doctor, however, charges what he sees fit for his service and the patient must pay the difference. In some localities the doctors have agreed with the insurance institution not to exceed a certain charge. This method of payment is liked by the medical profession, is fairly satisfactory to the societies, but the patients usually object to paying more than is covered by the insurance. The doctors here as elsewhere complain about the amount of clerical work, certificates, etc., for which they receive no pay.

An unusual provision is that the patient has to pay for medicines and appliances.

Contrasted with the English system, here the tendency is for the patient to receive too much attention; in England too little. In England the doctor may give a patient all the attention a patient needs without being suspected of mercenary motives but also is apt to neglect him. When the patient has to pay for drugs he is more apt to be satisfied with advice instead of the customary bottle of medicine.

In Norway the system is perhaps more satisfactory to the profession than in other countries. It is to be remembered that here there is one doctor to about every 1,800 people.

FRANCE

In France compulsory insurance is just being put into effect. The law is said to be a bad one and some think that it will be impossible to apply it. It is apparently a disappointment even to the beneficiaries, on account of the complications, formalities and small benefits. The medical profession has refused to accept the tariff proposed, and charge regular fees which are much greater than the amount allowed by the insurance companies. The Minister of Health has threatened to appoint full time salaried doctors to do the work.

DENMARK

It may be of interest to consider briefly the situation in Denmark. Here insurance is not compulsory in a legal sense, but the percentage of insured is about the same as in countries where the compulsory system is in force. In 1928 about 65 per cent of the population over 15 years of age was covered.

The insurance companies are under a certain amount of government control as to assets, minimum benefits, etc. The state subsidizes the companies to a certain extent, giving them much reduced rates in hospitals and other advantages.

In this country when a person receives aid from the public authorities he becomes a citizen of the second class. He is not allowed to vote, cannot be married without consent of the authorities, is not eligible for old age pension and must repay the government if it ever becomes possible.

These penalties apparently exert an indirect compulsion to insurance.

The Danish Medical Association represents the entire profession, makes contracts with the insurance companies and specifies the rate of compensation of the doctors.

Medical care rests with the doctor without control. Physicians are paid on a capitation basis in some localities and in others for services rendered.

The medical profession seems well satisfied under this system.

CO-OPERATION*

C. E. Rudolph, D.D.S.
Minneapolis

It IS indeed a compliment to be asked to appear before this group, and especially do I think the subject assigned very appropriate at this time. I do not say this because of the knowledge of undue friction between the two professions which we represent, but because of the social and political problems which confront us. I am certain that the practitioners of medicine in this Northern Minnesota Medical Association are fully aware of the present status of Medicine and Dentistry in their relationship to the body politic, but I am not so sure that all of us know the trends of lay thinking regarding our social position and economic responsibility to that body. If you have been following closely the better magazines and many of the daily papers of the day, you must realize that the thinking laity are studying the problem of medical care, and are devising ways and means in many localities for the dispensing of medical care. In many instances this is done under the direction of laymen. In other words, they are questioning our ability and inclination to solve the social problem which they feel now confronts this nation, and which involves us especially. I believe I said the thinking lay people were behind this movement. As evidence of this, I may cite the work of the committee on the Costs of Medical Care headed by the Secretary of the Interior, Dr. Ray Lyman Wilbur. No doubt you are quite familiar with its work to date; if not, each one of you who is in the practice of medicine should make it his business to become so. Much comment on the committee's work has already been in the press and the final conclusions are to be given to the press for public consumption.

If you will stop for a moment and ponder over this you will have perhaps one of two reactions: either you will feel perfectly safe with your phase of the problem as studied and conclusions arrived at by your members of this committee, or you will become indignant and question anybody's right to attempt to regulate your professional and business methods in dispensing that which you have educated yourselves to dispense.

Before any of us get excited let us see how much the government (village to the federal) regulates our daily work as we find it today. First, we probably pay much less than half of the cost of our education. The village, county, city, and state furnishes the rest. Next, the state examines and licenses us to practice. When we begin practice we find many barriers and restrictions set up to guide our daily work, which all of us know without mentioning. Next, we find that certain groups have attempted to furnish medical care through their officers or appointed officials, who, in turn, dictate or arbitrate the matter of costs, especially, with our professions. Along with this, we find some insurance companies, aided and abetted by the more or less socialistic elements, delving into the mysteries of medicine and attempting to dictate the medical welfare of the people who make up the middle economic class. We can't forget that each one of us must carry compensation insurance or not employ anyone. Many of us have had our patients' diagnosis made and the fee set for our services by a layman, usually an insurance adjuster, before we even see the patient, so that all we have to do is go to work. I am not saying these things in a spirit of criticism at all, but merely stating facts and the tendencies of the natural processes of evolution in medical economics. You and I, to date, are the progeny or product, if you like, of precariously guided medical forces. All or most of the tendencies have been toward scientific progress, much to our credit, with not too much thought given to the social problems involved, a little to our discredit.

---

*Presented at the annual meeting of the Northern Minnesota Medical Association, Hibbing, Minnesota, September 14, 1931.

We must recognize that the world is growing up. We have much older relatives, economically and socially speaking, on the other continents than we, and what has happened to them in their evolutionary processes is apt to happen to us. Our Committee on the Costs of Medical Care knows considerable about the processes which have finally socialized medicine in the other countries and our field men are still over there. Practically all of the civilized nations of the world have some form of socialized medical care. How we can sit idly by and smugly reiterate to ourselves that it can't happen here because of our different world economic level, is a mystery yet to be solved.

It has, until lately, been almost an insult to the intelligence of the mass of physicians and dentists of this country to even suggest that anyone was dissatisfied in the least with the medical care so generously dispensed. The statistical material gleaned by your committee should put a different meaning on the whole problem, and it is altogether too bad that each one of us has not the privilege of receiving all this material, digesting it, and then coming to conclusions which might otherwise seem so easily arrived at. At this point I am going to inject a few facts found by this committee on costs, and while I am doing all this talking I would not have you think that I have forgotten what my subject is.

With your indulgence I will spend a few minutes with factual material which may be used as a background for further discussion.

Population Data.—"Americans inhabit a territory of more than 3 million square miles, with an average density of 41 persons per square mile, ranging from 20,000 per square mile in Manhattan to less than 1 per square mile in Nevada. Twelve per cent lives in Metropolitan centers of a million or more, and 44 per cent in rural areas or communities of less than 2,500 persons. Nearly 90 per cent of the population is white and 10 per cent is colored; only 55 per cent is native white of native parentage."

Quite naturally we have not taken into consideration the elements of socialistic tendencies in the white group which represents the remaining 45 per cent. Most of these people have been through the socialistic medical evolution in some country of Europe. Many of them can think only of the benefits which they receive personally without having the least idea of what the effect has been upon the professions. Perhaps some of you don't know that medicine was socialized in Germany as long ago as 1883 by an imperial edict. This was the beginning and other central European countries followed. England's House of Commons passed socialized medical legislation in 1911; France in 1928. The history of these three countries regarding the methods used in passing this legislation is peculiarly interesting.

"Thirty-two per cent of the population in 1920 was under 15 years of age, 9 per cent was 15 to 19, 38 per cent was 20 to 44, and 21 per cent over 44. The age distribution is changing steadily because of decreasing birth rates and decreasing death rates. It has been estimated that, by 1975, 26 per cent of the population will be 50 years of age or over as compared with 16 per cent in 1920 and 9 per cent in 1890. In 1920 there were 104 males per 100 females. Six per cent of the people in the U. S. were illiterate in 1920; the percentages for negroes and foreign-born whites were 23 and 13 respectively. People in the United States must adjust themselves to a wide variety of climates, for temperatures have ranged from a maximum of 119 at Phoenix, Arizona, to a minimum of 45 below zero at Bismarck, N. D."

Economic Data.—"There were, in 1920, 33,000,000 males and 8,500,000 females (about 40 per cent of the total population) 10 years of age and over who were engaged in gainful operations. Thirty-one per cent of employed persons are engaged in manufacturing and mechanical industries and 26 per cent in agriculture, forestry, and animal husbandry." Thus 40 per cent of the people support the remaining 60 per cent, who include, of course, children, the aged and retired.

"The per capita income of the consumers of medical service (all the people) has been estimated for 1929, by the National Industrial Conference Board, at $692. This is merely an average, and does not at all represent the distribution of purchasing power. Of the 42 million occupied persons, about 86 per cent in 1918 earned less than $2,000 a year. At the other end of the scale, 2 per cent of earned incomes were more than $5,000 a year. Family incomes are somewhat larger than individual incomes. In 1926, about 48 per cent of all New York families had incomes of less than $2,500.

"The minimum cost of maintaining a 'fair American standard of living' for the family of an industrial worker has been estimated to range from $1,442 to $1,660, varying somewhat with the size of the city in which the worker resides. Since, according to 1918 figures, 39 per cent of the employed people had incomes of less than $1,500, they could not support a family at a 'fair American standard' with only one wage-earner. In some instances, of course, one family had two or more incomes."

"Extent of Illness and of Physical and Mental Defects.—A great variety of diseases and mental defects disable many members of the national community or prevent them from living in complete health. There are, on the average, two illnesses per person per year for which medical care is desirable or necessary and three defects per person, a considerable proportion of which probably requires medical treatment. About two per cent of the population of the United States are disabled by illness on any 'average' day of the year."

Two per cent of 123,000,000 would be 2,460,000 persons. The potential earning power of these persons might be estimated, say, at $2.00 per day, a wage far below the "fair American standard of living," and we have a daily loss of $5,852,000 in wages. This does not even come close to the actual loss, as you will recognize, but it gives a definite picture. The question arises, how much of this is preventable, and here is the crux of the whole situation.

Business men are interested in their losses sustained by the poor health of their employees. They are questioning the present methods of meeting their demands and in some cases they are taking the matter into their own hands and hiring medical services at so much per and getting results from a monetary point of view. You may have your own ideas of the standard of medical services dispensed by these hired servants, but the fact remains with the employer that in the aggregate he has saved money, and that talks with him. Just take this trend of medical care dispensation and glimpse, if you will, into the political and sociological possibilities, which are easily perceived by the smart politician and social worker, trained or untrained, and you see the reason for all the barriers we mentioned at the beginning. Project yourself just one step further and come to your own conclusions regarding state medicine or whatever name you wish to call it, for we are not standing still.

"Costs of Medical Care.—Various studies place the average cost of medical care at $70 to $230 per family per year, and estimates of the total for the United States as a whole range from $2,000,000,000 to $3,000,000,000 per year. The 'average' figures, however, are relatively meaningless in this field because of the extreme range among families, even among families in the same income group."

THE SUPPLY OF MEDICAL SERVICES

"I. The Supply of Medical Facilities.—Nearly 1,500,000 persons are now engaged in supplying various types of medical services to the people of the United States. Of these, 143,000 are physicians, and 67,000 are dentists. There are over 850,000 hospital beds in the country, of which 370,000 are in nervous and mental hospitals. There are at least 5,700 out-patient departments and other clinics in the United States, only a few of which are private group clinics.

"Although this existing supply of medical personnel, hospitals and clinics may be adequate or nearly adequate for the present existing demand, quite another question is raised if it is compared with the supply necessary to meet all the people's real needs.

"*II. Basic Costs of Medical Care.*—Medical service is not a 'free good.' Its costs of production are high, and must be met, either by the community or the individual consumer. The main items in the cost of production are the costs of training personnel, the capital investment in hospitals and in private practice, and the current expenses of hospitals and practitioners.

"1. *Costs of Training Physicians.*

"a. *Preliminary requirements.* A large percentage of medical students now take four years in liberal arts work before entering upon their medical courses.

"b. *Medical course.* Most medical courses now require four years of work, so difficult the student has little time for earning his expenses. (Less than $300 a year was the average for 518 students who reported earnings to the American Medical Association; less than half of the total number of students and any earnings.)

"c. *Internship and postgraduate work.* Practically all physicians now take an internship. In addition, the practice of taking special courses is growing among physicians who expect to specialize.

"d. *Total cost.* The cost of medical education to the student or his family is estimated to be about $4,500; an additional large item in the 'cost of production' of a physician is borne by the medical schools and hospitals and thus, indirectly, by the public.

"2. *Costs of Training Dentists.*—The dental curriculum increased in the majority of schools from two years in 1890 to four years by 1917. The total income of forty-two dentist colleges for the year 1924-5 was nearly $6,000,000, of which nearly $3,000,000 was paid by students, and $1,600,000 by patients.

"3. *Capital Investment in Hospitals.*—It is estimated that the capital investment of American hospitals now totals at least $3,125,000,000 and that at least $200,000,000 per year is spent in replacements, additions, and new projects. This ranks the 'hospital business' as one of the leading businesses in the United States.

"4. *Capital Investments of Individual Practitioners.*—In addition to the time and expense of education and training, the individual practitioners of medicine and dentistry frequently invest considerable sums in equipment. The mean average investments made during a ten year period by sample groups of practitioners covered in community surveys range from $1,860 to $3,310 for physicians and from $1,698 to $5,927 for dentists. The crude unweighted averages are $2,700 for physicians and $3,100 for dentists. These averages include only expenditures during a ten year period, while some equipment, of course, lasts longer than ten years. The total investment, therefore, for a physician's or dentist's entire professional life is undoubtedly greater than these amounts.

"*III. Current Expenses of Hospitals and Practitioners.*—Current hospital expenditures have been estimated at $4,000,000,000to $550,000,000 annually. They are large and tend to grow larger with the increase of hospitals and the growing complexity of care furnished therein.

"Private practitioners have current expenses for office rent, supplies, clinical and nursing assistance, laboratory costs, etc. The crude average ratio of expenses to total gross incomes as found in the community surveys is forty per cent for both physicians and dentists.

"*IV. Incomes of Practitioners.*—The 'average' net incomes of physicians and dentists in five community surveys are:

	Physicians	Dentists
Shelby	$3,419	$2,744
Philadelphia	5,156	5,102
Detroit	5,596	6,067
Vermont	4,998	4,187
San Joaquin	7,187	4,875
Crude unweighted average	$5,271	$4,595

"These averages, however, like the average incomes of other people, are far from representative of the bulk of the practitioners. A distribution of the incomes of physicians and dentists in Philadelphia indicates that one-half of the physicians earn less than $4,207 and one-half of the dentists less than $4,000. The same general type of distribution was found in Detroit. Private duty nurses in Philadelphia report annual incomes averaging about $1,300 (a more representative figure in this case)."

During the last few months much other data has been collected: Dental Income Study, Medical Student Costs, Costs of Equipping Dental Office, etc. In each of these studies and all those that have been made up to last May certain definite tendencies are noticeable. For instance, just one, the tendency to specialize in some branch, leaves the number of general practitioners below actual needs in certain districts, and above in others. We note from our field studies that the so-called specialist these days has a larger income than a general practitioner, and quite naturally the rank and file want to become affluent. Have you stopped to think what the 86 per cent of the people of this country are going to use for money when they are directed to employ a specialist in the present order of things?

Here is a bit of interesting data found to be true in Shelby County, Ind. The people of this county spend more for patent medicine in a year than they do for the services of physicians. This opens the field for "lay medical education," if I may use the caption. How far should we go with this phase of the problem? How much does the public deserve and where should it come from? It is just a possibility that we have been so interested in the purely scientific phase of our professions that we have forgotten to dispense the proper educational propaganda to insure our professional lives. I know how hide-bound you and I are in our ethics and we are both afraid to step out with a new program, but if we do not, some one who knows a whole lot less about our ethical and altruistic tendencies than we do ourselves will, and by popular consent, not ours. We will have to acquiesce, as the professions have had to do in the older countries.

Not many of us are hankering to go to Austria or England to practice. On the other hand, not many of us are trying to devise ways and means whereby our existence as private practitioners will be insured in this country. This brings me to the subject of the evening, and here I cannot refrain from giving a little historical data regarding the entry of the three countries, I have already mentioned, into socialized medicine.

I mentioned that Germany was socialized by imperial edict. This happened almost over night and it was done to satisfy pressure brought to bear by the working classes. The professional men were not taken into consideration, and medicine has not improved perceptibly, especially since the war, and now less than 5 per cent of the physicians in Germany have private practices.

In England the people of the lower economic classes put on the pressure and, while the process of getting the law through took considerable time, the professional men simply tried as individuals to stem the tide by saying "it can't be done" and "it must not be done," and finally in 1911 it was done and the physicians and dentists have been fighting for twenty years to make it possible for a patient to choose his own physician. This was finally accomplished one year ago last July.

France has a little different story. A number of years ago, the professions realized that it was just a matter of time before the issue of socialized medicine would come directly before their lawmaking body. The socialistic tendencies were definite and easily recognized. Men of sound judgment were sent to the surrounding countries and all available material gathered and studied by the professions. The professions, as a result, united into a working body and became distinctly politically minded. By the time the laws were drafted and finally passed, every governmental committee of any kind which dealt with health measures in any degree had at least one strong member from the medical and dental professions as a member of it, and the result is that the most healthy condition, from a medical economic point of view, obtains in France. The insurance companies happen to be in the unfavorable position. The outcome in France to date is the result of concerted effort on the part of both professions. It has taken a solid front to accomplish what they have done. I have not the time to go into details regarding the exact status in any of these countries, but sufficient to say, that from a medical economic point of view, which, by the way, is at all times altruistic, France leads Europe.

The spirit of coöperation must pervade the medical groups in this country to insure the proper guidance of the tendencies of socialized medical legislation. It is foolish to think we have no such tendencies. All but four states have compensation laws. All the foundations have been laid. Our unhealthy complexes, if we have them, must be put aside in oncoming years if we can hope to cope with the problems which will be forced upon us as sure as fate. Perhaps you are beginning to feel sorry for me in my apparent sentimental state of mind. I am well aware that sentiment alone does not suffice in arguing a case before logical judgment. On the other hand, mere statement of fact will scarcely ever win a debate with the popular mind as the judge. Combine logic with the proper amount of sentiment and you have an appealing and convincing prescription. For sentimental reasons, I might call a plumber to plaster my house, but as a matter of fact I would have a terrible mess of things if he attempted the job. By the same token, why should an insurance adjuster, politician, or any other unqualified person dictate the medical welfare of this nation? Remember we are not going to be called into politics or social service by the laity. It is our business, and we should be about it. We are part of the so-called learned professions which comprise the upper fifth of the intellectuals of this country, and are expected to lead the way in our particular phase of life. Any misstep on our part might mean the hampering of our scientific, social and economic status for a generation or more to come.

In conclusion, I should like to make this very earnest appeal. Let every man in each profession representing medical care become interested to full capacity in the political and economic, as well as professional side of his profession. Let each man be tolerant of his brother practitioner and be willing to work in harmony for the upbuilding of the professions at all times, and especially stand as a man against any belittling or disorganizing propaganda which might be brought to bear from outside sources. Finally, it is my conviction that the three principles proposed by Dr. Ray Lyman Wilbur will not only safeguard the public, but the professions as well, and they are:

"1. The personal relation between patient and physician must be preserved in any effective system of medical service.

"2. The concept of medical service of the community should include a systematic and intensive use of preventive measures in private practice and effective support of preventive measures in public health work.

"3. The medical service of a community should include the necessary facilities for adequate diagnosis and treatment."

SURGICAL CONSIDERATIONS OF ANGINA PECTORIS*

Alfred W. Adson, M.D.
Rochester, Minnesota

The syndrome described as angina pectoris represents a complicated pathologic cardiac mechanism; hence it is unreasonable to expect any one form of medical or surgical treatment to relieve all anginoid pains. The paroxysmal attacks are believed to be initiated by anemia or anoxemia of the cardiac muscle under increased exertion. The constant pain in the precordium which radiates down one arm or both arms is due probably to neuritic changes accompanying the organic disease of the aorta, coronary vessels and myocardium.

Various opinions are held concerning the pathologic etiology. Some observers hold that sclerotic changes in the aorta are responsible for the paroxysmal attacks, and many others believe that the sclerotic changes in the coronary vessels with the associated myocardial degeneration are responsible for the attacks. However, since many attacks are initiated by emotion, aggravated by exertion and are temporarily relieved by vasodilating drugs, it is fair to assume that vasomotor spasm of the coronary arteries or their terminal branches contribute to the syndrome, and that surgical intervention may be called on to assist in relieving the vasomotor or painful stimuli.

The mechanism of the heart is controlled by efferent and afferent nerves from the vagus and sympathetic nerves, in addition to its intrinsic nerves. The depressor nerve has its origin in the superior sympathetic ganglion and in the upper ganglion of the vagus nerve. Following the fusion of the nerves from these two sources it travels free in the neck to end in the suprasigmoid portion of the aorta, and according to Koster and Taschermak, it is known to be a purely sensory nerve to the aorta. Other vagal fibers communicate with the superior, middle and inferior cardiac nerves and according to Green are capable of influencing acceleration as well as carrying depressor stimuli. The sympathetic accelerator nerves, according to Ionescu and Enaschesu, and to Cannon and his co-workers, take origin from the upper five thoracic ganglia and enter the cardiac plexuses by the cardiac nerves and by direct communication from the third, fourth and fifth thoracic ganglia. The vasomotor stimuli from the upper thoracic sympathetic ganglia pass through the upper thoracic trunk and the three cervical ganglia to enter the superior cardiac nerve, thence to be disseminated through the cardiac plexus to the coronary arteries. According to Ranson, Edgworth and Kuntz, painful stimuli from the cardiac and coronary mechanism reach the upper part of the thoracic portion of the spinal cord by medullated fibers which pass through the middle and inferior cardiac nerves, middle and lower cervical ganglia, the two upper thoracic ganglia, the white rami communicantes, and the dorsal roots.

---

*From the Section on Neurologic Surgery, The Mayo Clinic, Rochester, Minnesota. Abstract of paper read before the Minnesota Society of Internal Medicine, St. Paul, November 1, 1931.

Jonnesco, in 1916, at the suggestion of Francois Franck, resected the cervicothoracic sympathetic trunk including the middle cervical and stellate sympathetic ganglion for angina pectoris. Coffey and Brown advocated resection of the superior sympathetic ganglion on one side or on both sides. Cutter, Penfield and Gilbert, Kerr and many others have reported numerous experiences in the treatment of angina pectoris by sympathetic cervicothoracic ganglionectomy and trunk resection by the anterior Jonnesco approach. White had advocated paravertebral injection of alcohol of the upper five thoracic nerves on the left side for anginoid attacks.

Since the results have varied from complete success to partial success and failures, I have been impressed with the fact that the good results of surgery will depend on the more accurate selection of operation for the individual patient. In order to arrive at such a selection I believe much can be learned in comparing the symptoms, pathologic changes, and results obtained by medical treatment, and by sympathectomy in disease of the peripheral vessels of the extremities with those of the coronary vessels of the heart, as it is my impression that many analogous lesions exist.

Raynaud's disease of peripheral vessels may be compared with angina pectoris of the mild type in young subjects, in whom arteriosclerotic changes cannot be demonstrated. But as Raynaud's disease progresses, trophic lesions soon develop and give rise to degenerative lesions in the skin, subareolar, fibrous, nervous, muscular, ligamentous and osseous tissues which may be compared with the myocardial changes and be responsible for continuous pain and the intermittent claudication on increased exercise. The pathologic changes and symptoms following arterial sclerosis of the arteries of the legs and feet unquestionably simulate the cardiac syndrome in senile patients. The patients complain of continuous pain and intermittent claudication, and neither group receives relief from vasodilating drugs or from operation. The pain is only relieved by interrupting the afferent fibers either by section or by destruction of nerves with drugs.

It is possible that thrombo-angiitis obliterans with its associated vasomotor spasm may be the predominating factor in the production of coronary infarcts in middle-aged men, since I have seen at necropsy lesions of the coronary arteries that were similar to those previously recognized and demonstrated in the vessels in the feet and legs. The occlusive lesions due to arterial sclerosis of peripheral vessels which result in pain and gangrene again appear to be analogous to the coronary disease, only death ensues before the terminal stages of degeneration of muscle take place.

Therefore, in the light of anatomic and pathologic evidence one might assume that angina pectoris occurring in a young person might be due to vasomotor spasm of the coronary arteries, which explains why vasodilating drugs or any operation that divides nerve fibers carrying vasomotor responses gives relief. It is in this group that single or bilateral superior cervical sympathectomy has been so effective.

If, however, one were dealing with two etiologic factors, that is, organic lesions of the coronary arteries with a superimposed vasomotor spasm on normal coronary branches, superior cervical ganglionectomy would fail to give the results accomplished by a Jonnesco operation, since the later operation not only includes the vasomotor fibers but many of the afferent pain fibers returning through the middle and inferior cardiac nerves. When this operation is indicated the posterior approach to the cervicothoracic ganglion is more effective, since there is less chance of missing the first thoracic ganglion by the posterior approach than there is by the anterior superior approach. However, if the cardiac lesion is void of any vasomotor phenomena and is due to coronary or aortic sclerosis, it is readily understood why patients may continue to have light attacks of pain, even though both cervicothoracic ganglia have been removed, since the fibers of the depressor nerve and the second, third and fourth thoracic nerves receive afferent fibers carrying painful stimuli independent of the superior, middle and inferior cardiac nerves, and it is in such cases that vasodilating drugs likewise fail and paravertebral alcoholic injections have to be resorted to for symptomatic relief.

Therefore, surgical treatment of angina pectoris is indicated if patients are young, if they present vasomotor phenomena, and if they would otherwise be compelled to undergo medical treatment for years. Sympathectomy is indicated in conjunction with medical treatment when either treatment alone fails to give complete relief. Paravertebral injection of alcohol of the upper thoracic nerves is a procedure that is indicated in extremely senile patients when medical treatment fails, and when the lesion is due to sclerotic changes rather than to vasomotor spasm.

AIDS IN THE DIAGNOSIS OF HIP-JOINT DISORDERS*

George A. Williamson, M.D.
Saint Paul

THE hip-joint provides more difficulties than any other joint, to beginners and experienced alike, when it becomes necessary to determine the nature of some disturbance of function due to disease or injury. The depth of the joint from the body surface makes direct palpation impossible or unreliable and one is forced to rely more and more upon signs and various measurements in arriving at a diagnosis. A proper understanding of some of the common signs and measurements is necessary if one is to reduce his percentage of error in diagnosis to a minimum. Usually a child with a limp reporting for treatment causes some worry and consternation when it walks into the office, and it is only by most painstaking palpation, mensuration, radiographic and laboratory examinations that one is able to arrive at the correct interpretation of the existing condition.

It is not the purpose of this brief paper to discuss at length all the details of various signs but to merely refresh in your minds the ones most frequently used, and therefore most practical and dependable.

The hip is a ball and socket joint, stable, strong, and freely movable by virtue of its deep, solid bony socket made up of parts of the ilium, pubis and ischium, its reinforcing ligaments and powerful muscles. This joint is second only to the shoulder in its mobility and is supplied with checks against an excessive range of motion. As an example one finds the iliofemoral or "Y" ligament of Bigelow preventing hyperextension beyond the normal 45°. In like manner flexion, adduction, abduction and rotation are checked by ligaments, the various muscles attached about the hip joint, or by the approximation of adjacent parts of the body.

The most important aid in the diagnosis of hip disease is a knowledge of the etiology of changes in the gait. It is quite essential for the patient to be stripped for the examination. Before any other examination is made the patient should be asked first to stand and secondly to walk across the floor so that the erect posture and gait may be studied. There is no doubt that careful observation from these two aspects saves a great deal of time as the attention is immediately directed to the abnormal extremity.

Pain in the hip causes a very characteristic limp which can hardly be mistaken once it has been seen. Putting the weight down on the extremity of the affected side causes pain which results in the patient flinching and hopping quickly onto the other leg. The steps taken on the affected side are very short and when standing all the weight is borne on the normal leg.

A limp caused by a flexion deformity necessitates a sudden forward movement of the entire body as the weight is brought down on the affected side, giving to the gait a typical bowing movement. When standing erect the flexion of the hip is compensated for by increasing the lordosis of the lumbar spine. Most of the weight is borne on the normal side or on both feet by standing on the toes with the affected foot held in the equinus position (Fig. 1).

---

*From the Department of Orthopedic Surgery, The Miller Clinic, St. Paul.

When the hip is deformed in the abduction position the extremity is held away from the midline of the body as it is apparently lower than its normal companion. When the deformity is one of adduction the hip of the affected side is very prominent, the extremity apparently shortened, and the gait has a characteristic lurch. When observed from in front the relationship of the adducted or abducted extremity to the pelvis remains unchanged during every phase of a step whereas normally this relationship changes with each phase.

If the extremity is shortened the patient walks on the toes of the affected side or due to the dropping of the pelvis on that side with each step he is obliged to lean the entire body toward the affected side as he steps, conpensating for the shortening when standing by the development of a postural or static scoliosis which later becomes a structural one.

The limp of a congenitally dislocated hip is typical in both the unilateral and bilateral cases. Due to the dislocation of the head of the femur from the acetabulum, each time the patient steps on the affected side there is no fixed point of support for the body weight, and as a result the pelvis drops on the unaffected side, producing a lurch in the gait, with the patient rising on the stable side before making his next step. If both hips are dislocated the gait can be likened to that of the waddle of a duck. A marked lordosis with prominent buttocks is also a conspicuous feature, as is external rotation of the feet, and the widening of the perineum.

After a study of the gait and attitude of the patient one may proceed to the true determination of the nature of the deformity by measurement of the ankylosed positions of the joints, range of motion in partially ankylosed joints, stability of the joints on weight bearing and the comparative length of the extremities. This examination concerns chiefly the topographical anatomy of the hip joint.

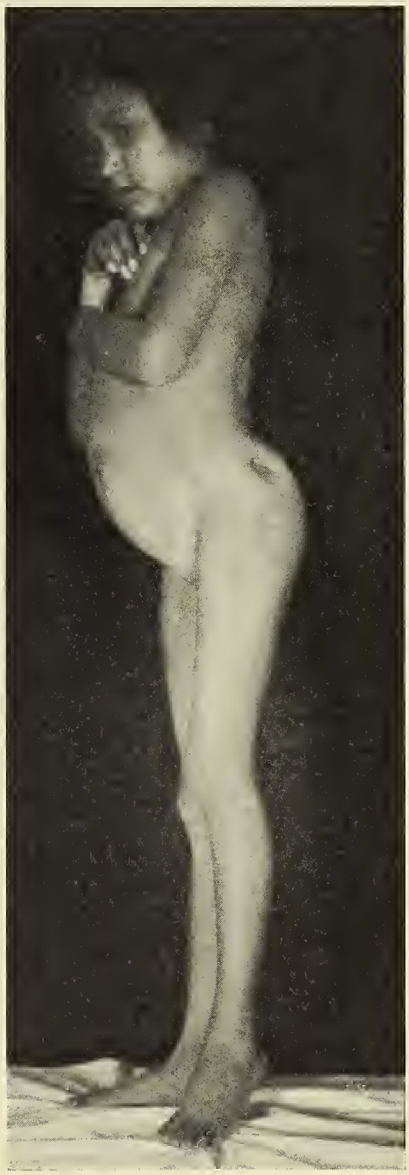

Figure 1. Lateral view of a patient with hip joint ankylosed in a flexed position shows the marked increase in lumbar lordosis necessary to get the limb into the vertical axis of the body. The foot on the side of disease is held in equinus so as to get weight-bearing on both feet by standing on the toes.

In order to get weight-bearing on both feet it is necessary to keep the foot in equinus on the side of the disease, making up for the shortening to some extent.

There are many lines and prominences on the body surface which may be utilized for determining changes in the position of the head of the femur in respect to the acetabulum, due to dislocation, fracture, disease and destruction of either part, or changes in the relative positions of the greater trochanter and head of the femur such as one finds in alterations of the angle of the neck of the femur in the so-called coxa vara and coxa valga.

The prominences used to determine various lines are the anterior and posterior superior iliac spines, the tip of the greater trochanter of the femur, and the tuberosity of the ischium.

It is intended here to enumerate a number of these signs indicating wherever possible the comparative value of each.

Bryant's line or triangle is probably the most universally used because of the possible accuracy of the measurements. With the patient on his back on a table a perpendicular line is dropped from the anterior superior spine forming one side of the triangle. A line is then drawn from the tip of the great trochanter to the anterior superior spine forming the hypotenuse of the triangle. A third line, drawn at right angles from the perpendicular line to the tip of the trochanter, forms the base and it is to this line that Bryant refers chiefly. Normally the length of this base line should be equal on both sides. If the line is shorter than on the normal side it means that the trochanter is in a relatively higher position than normal due to dislocation of the hip, destruction of the head or neck of the femur or roof of the acetabulum by disease or fracture, or to a decrease in the angulation of the neck of the femur with the shaft thus approaching a right angle as in coxa vara. In contrast, if the line is longer than on the normal side we may have dislocation of the hip below the acetabulum, or a change in the angulation of the neck of the femur with the shaft approaching a straight line as in coxa valga. In Bryant's opinion the chief value of this line was to demonstrate impaction of a fracture of the neck of the femur although we have come to use it more generally.

Nelaton's line may be placed next in order as it is probably the second in usefulness and in

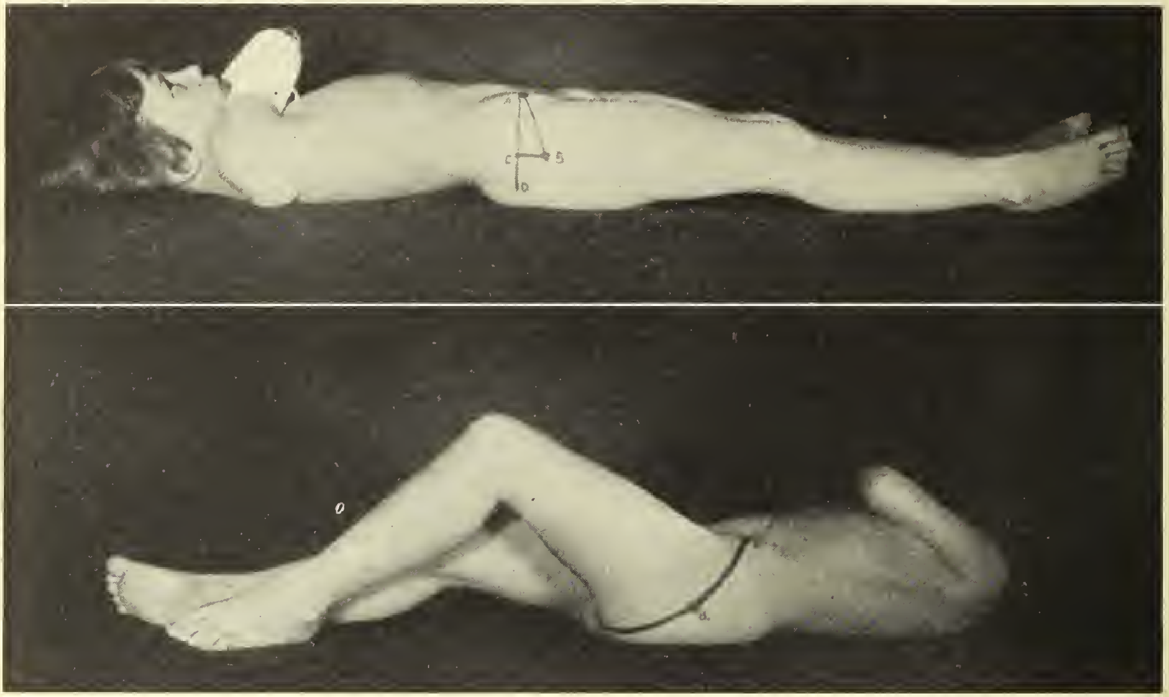

Figure 2. *(above)* Bryant's line or triangle.

With the patient lying on her back on a table a vertical line is dropped from the anterior superior spine (A) to the table. A line (A-B) is then drawn from the anterior superior spine to the tip of the greater trochanter. A line (B-C) is then drawn from the greater trochanter perpendicular to (A-D) forming the base-line of the triangle A-B-C. This triangle is referred to as Bryant's triangle or the base-line as Bryant's line.

(below) Nelaton's line.

With the hip flexed about 50° a line ABC drawn from the anterior superior spine to the ischial tuberosity passes through the tip of the greater trochanter (B).

familiarity. If the anterior superior spine is joined to the tuberosity of the ischium by a straight line the tip of the greater trochanter will be crossed by this line. The trochanter will be found riding above this line in the same conditions which cause a shortening of Bryant's line and riding below this line with lengthening of Bryant's line (Fig. 2).

Among the other less familiar lines are:

1. Petersen's line which is a horizontal one drawn through the upper border of the symphysis pubis. Normally the tips of the greater trochanters are level with this line. Its usefulness is limited, however, as it is difficult in many patients to define the upper border of the symphysis.
2. Shoemaker's line is interesting especially in congenital dislocation of the hip. This is merely the prolongation of the line joining the tip of the greater trochanter to the anterior spine across the median line of the abdomen. Normally this line bisects the median plane at or above the umbilicus, whereas, if the hip is dislocated or involved by any of the factors accompanied by a shortening of Bryant's line the median plane is crossed below the umbilicus (Fig. 3).

The gluteal folds form a horizontal line if the legs are of the same length and form an angle with the horizontal if the length of the two legs is different.

Morris' bitrochanteric test is useful at times although one can obtain almost as reliable information by speculation and Bryant's line. A measuring stick calibrated from the center toward each end is placed so that the center corresponds to the median plane of the abdomen. The distance of each greater trochanter from the mid-line is measured. Destruction of the neck of the femur, the head, or the acetabulum due to fracture or disease may lead to a loss of length in this line as compared to the normal side. For practical purposes this test may be cast aside.

In addition to information regarding the relative position of the head of the femur and greater trochanter to the acetabulum one must frequently make comparative measurements of the two extremities as regards length, flexion, adduction, abduction, and rotation. It is of prime importance in the correction of hip deformities for one to be thoroughly conversant with the methods of measuring the length of the legs as well as the degree of adduction, abduction, or flexion in deformities.

Restriction of flexion probably occurs most frequently in hip deformities although it is rarely found unaccompanied by adduction or abduction limitations. It is very important to differentiate a permanent flexion deformity due to disease of the hip joint from that often found accompany-

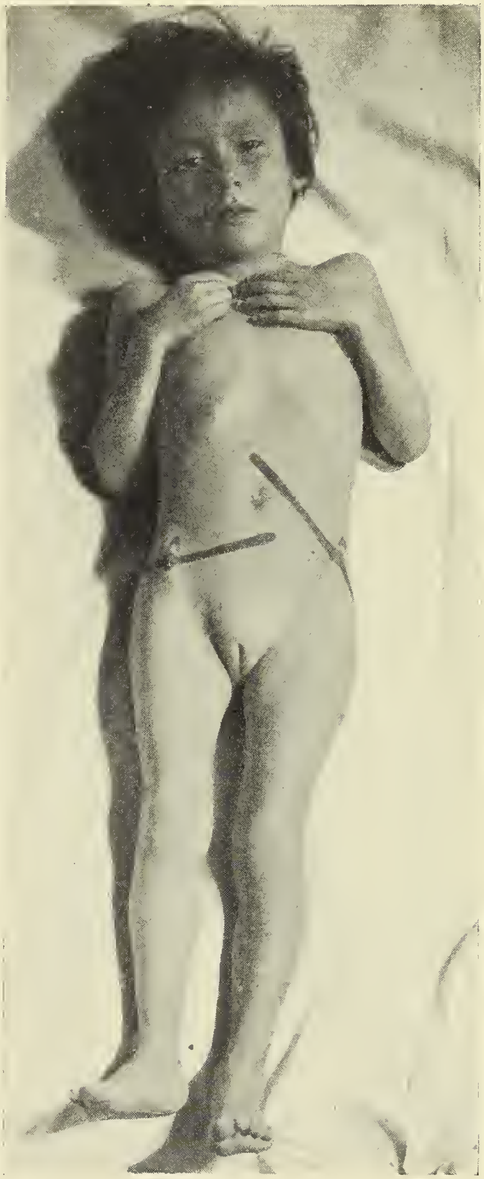

Figure 3. Shoemaker's line.

A line connecting the greater trochanter with the anterior superior spine if extended onto the abdomen crosses the mid-line at or above the umbilicus. If the hip is dislocated as on the right side in this illustration the line will cross the midline of the abdomen at a point below the umbilicus.

ing a psoas abscess. In this latter condition the only motion limited is that of extension. It is possible to flex the thigh beyond the deformed position as well as to rotate it throughout its normal range without pain. If the deformity is due to hip joint disease, motion if at all possible will be accompanied by pain. The limitation of motion will be present in all directions due to destruction of the articular surfaces of the bones, involvement of the ligaments and capsule, or deformity of the head of the femur or of the acetabulum.

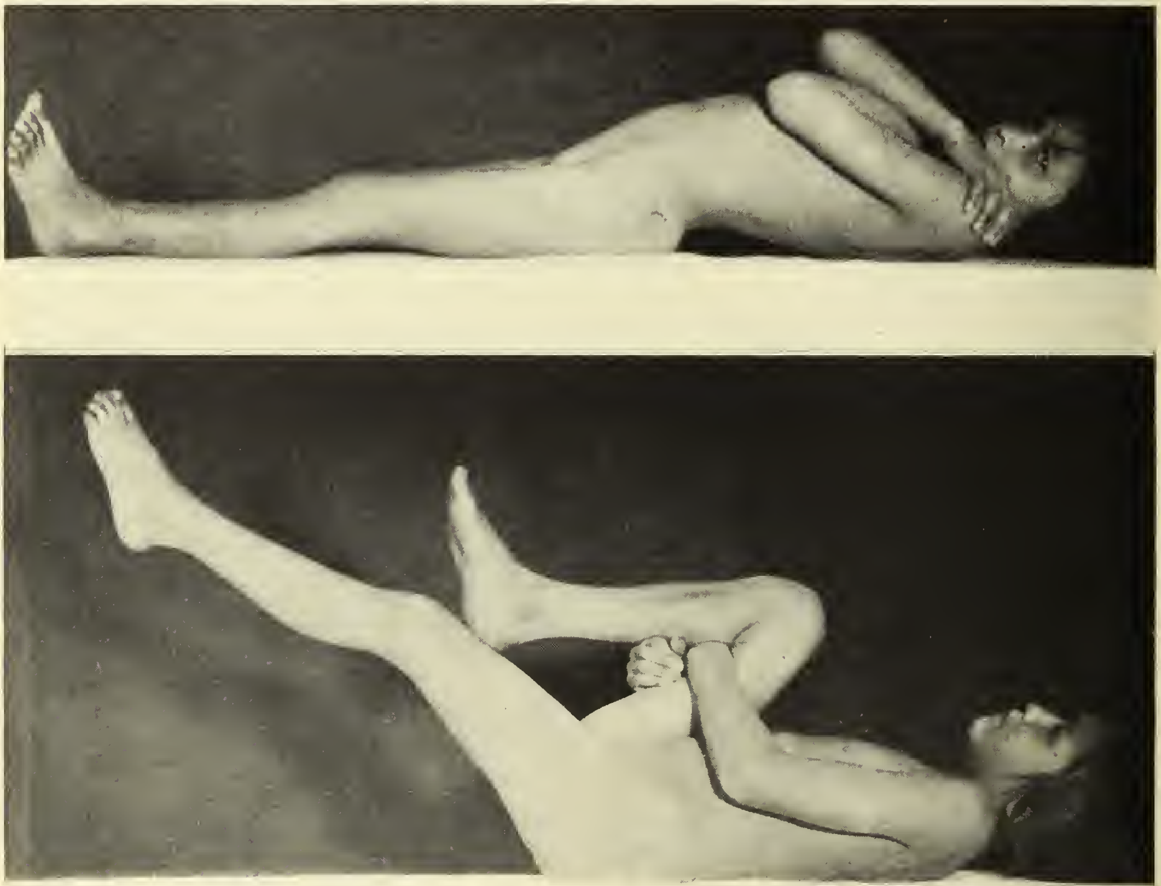

Figure 4. Thomas test for hip-flexion.

The patient is placed on the back flat on a table. If the legs are completely extended as in the upper view the lumbar spine becomes arched forward if there is a flexion deformity in the hip.

In the lower view the patient grasps the normal extremity with both hands, flexing it firmly against the abdomen, thus fixing the pelvis and flattening the lumbar spine.

The other extremity then assumes a position at an angle with the horizontal equal to the degree of flexion present in the hip.

Normally flexion of the hip is possible from the horizontal up to a point at which the thigh comes in contact with the abdomen if the knee is flexed. In deformity the hip may be stiff in any position inside this range. As the "position of optimum function" of the hip as regards flexion amounts to 10°-15° it is necessary to be able to determine whether an increase or decrease of flexion is present. It is true that many times one is able to judge fairly accurately the number of degrees of angulation. However, the goniometer or some mathematical table should be used for exact determinations.

The Thomas test for hip flexion should be understood as it is a prerequisite for accurate measurement of the degrees of angulation.

The great flexibility of the spine allows a patient to compensate for a marked flexion deformity of the hip, by increasing the normal mild lordosis in his lumbar spine (Fig. 1). If the flexion deformity is not marked it is often difficult to detect this compensatory adjustment. That it is impossible to extend the flexed ankylosed hip without producing lordosis in the lumbar spine forms the foundation for the Thomas test (Fig. 4).

The patient is placed in the horizontal position on his back on a table or other hard flat surface. A bed will not do. He is told to hold the normal leg flexed firmly against the abdomen, using both hands for this purpose. By this means the lumbar spine is held flattened against the table and

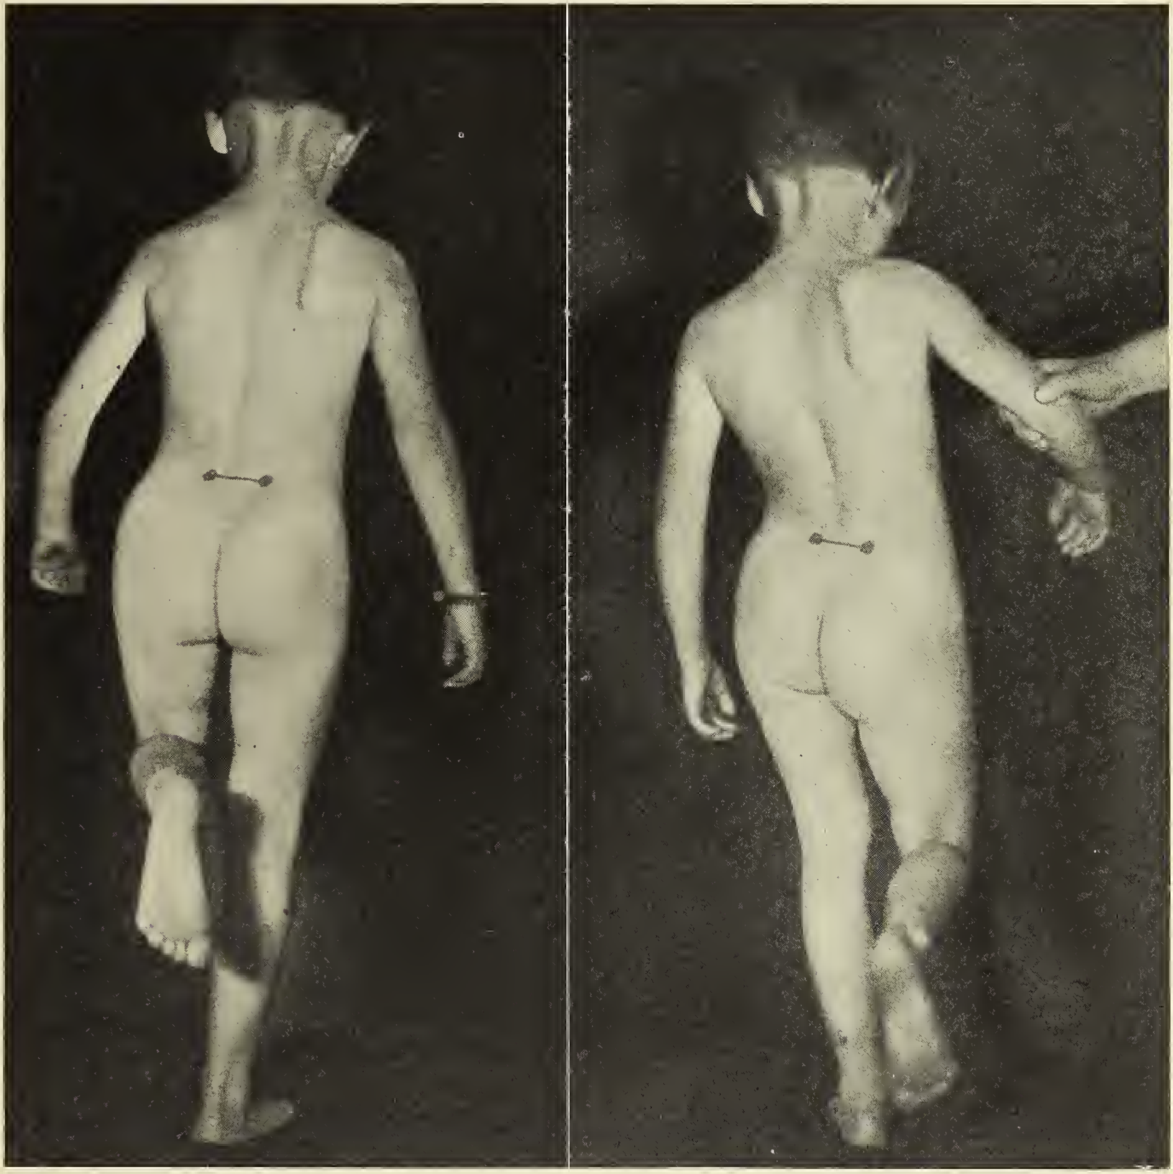

Figure 5. Trendelenburg sign.

A shows the patient standing on the normal extremity with the pelvis raised on the opposite side. Figure B shows how the pelvis drops when the patient stands on the dislocated extremity. The instability of the left hip makes it necessary for the patient to be supported when the weight is borne on the left leg.

The transverse line connects the posterior superior iliac spines.

the pelvis is fixed. The other extremity with the knee held straight assumes an angle with the horizontal equal to the number of degrees of flexion deformity in the hip. This angle may be measured by a goniometer or by taking the vertical distance to the table from a point on the leg 24 inches distal to the greater trochanter and consulting the table devised by Kingsley in 1888 for estimating the degrees of flexion. It is necessary to have ready access to Kingsley's table is one is to be able to utilize this method conveniently.

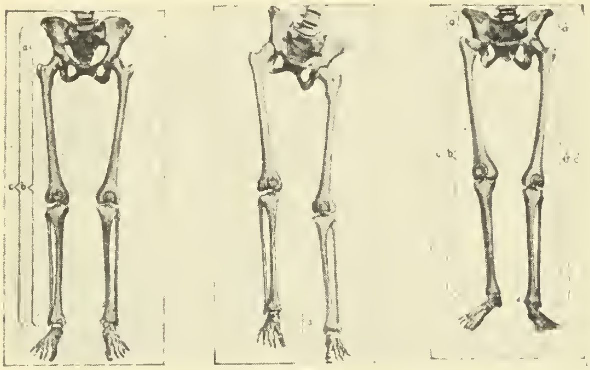

Figure 6. (From De Quervain's Surgical Diagnosis)

This is intended to show on the skeleton what is meant by apparent and real shortening. A is the distance from the greater trochanter to the level of the anterior superior spine previously referred to as Bryant's line. C is the measurement usually made from the anterior superior spine to the malleolus of the tibia and referred to as the actual length of the leg.

In the central figure the difference in the length of the legs produced by tilting the pelvis or adducting the extremity is shown. The actual length from the anterior superior spine to the malleolus is the same although the adducted leg is apparently shorter. The distance from the umbilicus to the malleolus on the right side is shorter than the distance between the same points on the left side. This difference is the apparent shortening.

The figure on the right shows real shortening due to a fracture of the neck of the femur. This shortening would be shown as a shortening of Bryant's line and a diminution in the distance from the anterior superior spine to the malleolus when the pelvis was held level.

In addition to being able to measure the amount of flexion deformity in a stiffened hip it may be necessary to determine the range of flexion in a partially stiffened hip. After flexing the normal thigh on the abdomen as in Thomas' test so as to fix the pelvis one is able to determine the degree of further flexion possible before resistance is met. By making measurements as described in Kingsley's table or using the goniometer, accurate readings of this range of motion may be obtained.

A word of caution may be inserted here relative to using the Thomas test in acute hip lesions. Due to the extreme degree of pain often present it is necessary that the affected limb be supported by the examiner when the normal limb is flexed to the abdomen

The Trendelenburg sign is a true indicator of the weight-bearing stability of a hip joint. Standing upon a normal extremity the opposite leg is raised from the floor by bending the knee. In order to keep the center of gravity of the body directly over the center of support, the pelvis is raised by the lateral abdominal and spinal muscles on the side of the flexed knee while the gluteal muscles on the weight bearing side immobilize this hip. If the hip is dislocated on the weight-bearing side it is impossible to obtain a fixed point for support, namely, the head of the femur in the acetabulum and the lateral abdominal muscles of the opposite side cannot function as before. As a result, the pelvis drops and the patient falls to the side away from the weight-bearing leg.

If both hips are dislocated this dropping of the pelvis on the side opposite to that of support is obtained when each extremity, in its turn, is raised. The patient has a bilateral Trendelenburg sign. It is not hard to see the effect upon the gait that this instability of the hip or hips would have (Fig. 5).

It might be well to mention at this point that a positive Trendelenburg sign is also obtained in at least three other conditions, namely: (1) coxa vara; (2) ankylosis of the hip in adduction; and (3) infantile paralysis involving the lateral abdominal and spinal muscles.

While on this subject of congenital dislocation Malgaigne's sign might be called to mind. The patient is placed on the normal side on the table with the affected hip and the knee flexed. The examiner grasps the uppermost extremity by holding the knee in one hand and placing his other hand on the buttock. One pushing dorsally in the long axis of the flexed femur a prominence is produced in the buttock. If only one lump is felt it is the greater trochanter and the hip is not dislocated. If two lumps are felt they are the head of the femur and the greater trochanter and the hip is dislocated.

It seems hardly necessary to attach a proper name to such an obvious finding but as the test may appear in the literature it should be mentioned at this time.

Shortening of the extremity may be actual or apparent. The differentiation between these two conditions is important and sometimes difficult to determine.

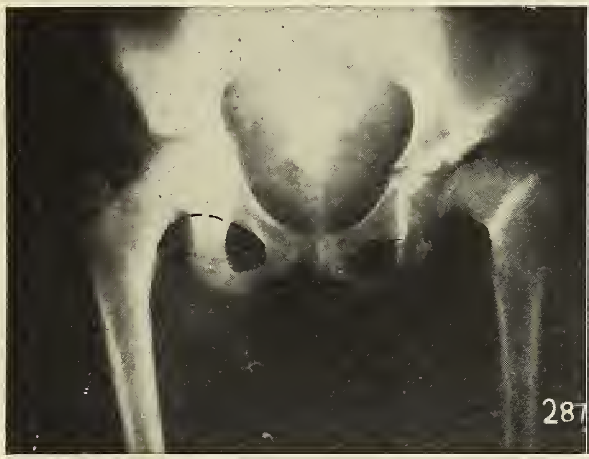

Figure 7. Shenton's line.

This is a moderately severe example of the distortion of Shenton's line in a case of coxa plana. The right hip is normal.

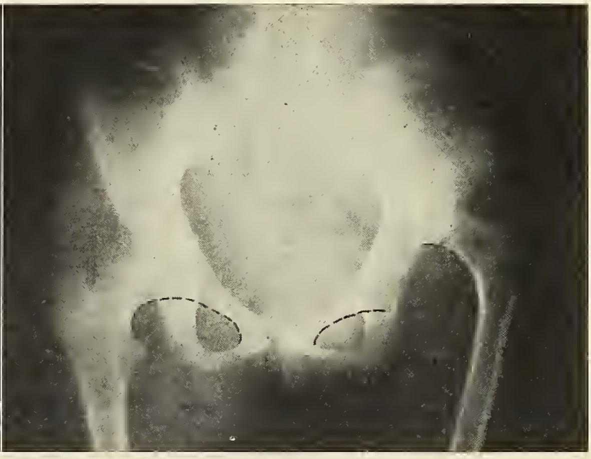

Figure 8. Shenton's line.

The distortion of Shenton's line found in dislocation of the hip is very marked, as shown in this view. The right hip is normal.

Before measuring the length of the legs one must be sure that the pelvis is horizontal in both planes and that both extremities bear the same relation to the perpendicular dropped from the line connecting the two anterior superior spines in so far as flexion, adduction and abduction are concerned.

The measurement is made from the under surface of the anterior superior spine to the tip of the medial malleolus or the sole of the foot and is probably more accurate if measured to this latter point.

Actual shortening is due to retardation of growth from disuse or disturbance of epiphyseal cartilage from congenital lack of development from disease, traumatic destruction, or displacement of the head of the femur or acetabulum.

Apparent shortening or lengthening is due to adduction or abduction deformities of the hip joint as the case may be. These apparent changes in length may be determined by measurement from the umbilicus to the medial malleolus of the tibia. If the hip is adducted the pelvis is tilted upward on that side so that the malleolus is brought nearer the umbilicus and an apparent shortening results. If the hip is abducted the pelvis tilts downward and apparent lengthening results. When the apparent shortening is greater than the real shortening the hip is adducted, and if the apparent lengthening is greater than the real lengthening the hip is abducted.

These measurements of apparent and actual shortening can be utilized to determine in degrees the extent of the adduction or abduction deformity of the hip. By taking the difference between the actual and apparent shortening and determining the width of the pelvis across the anterior superior spines one is able to use a table published by Lovett in 1888 to determine the number of degrees of adduction or abduction present. Here again it is necessary to have ready access to a table of figures in order to obtain the correct reading. Both the table and Kingsley's table mentioned above may be found in Whitman's Orthopedic Surgery or other similar textbooks (Fig. 6).

It is only by a special technic mentioned by Adams recently that one is able to measure adduction or abduction deformities on the radiograph. For all practical purposes it is not necessary to make an accurate measurement of adduction or abduction. If the anterior superior spines are joined by a horizontal line the degree of variation to either side from the perpendicular to this line can be estimated fairly accurately visually. The goniometer may be used if actual readings for purposes of record are desired. In the growing child the length of the legs changes rapidly when the hip is ankylosed in the adducted or abducted position due to the increase in the width of the pelvis. One is tempted to ask why so much care is taken to put the hip at a carefully predetermined angle for ankylosis so that the legs will be of the same apparent length, knowing that this apparent length will change very soon with the growth of the pelvis.

From the radiological standpoint one does not have so many signs or measurements to remember. Of course, the radiograph demonstrates conclusively such conditions as pathological changes in and about the hip joint, congenital dislocations, traumatic lesions and so on, but sometimes the involvement is so mild that unless there are definite points or lines to be used as landmarks, variations from the normal may be missed.

In 1911, E. W. H. Shenton described a line bearing his name which acts as a very useful guide in the radiography. This line drawn along the outline of the lower surface of the neck of the femur and the upper rim of the obturator foramen forms an unbroken sweeping curve. If, for any reason, the head of the femur assumes a higher position on the pelvis on one side than on the other the curved line is broken. This forms a reliable guide directing the attention to the abnormal hip (Figures 7 and 8).

A straight line passing through the center of the sacrum and the symphysis pubis furnishes a useful fixed median plane from which the degree of adduction or abduction of the hip joint can be estimated. Accurate measurement cannot be made for recording unless the radiographs are taken with a definite technic such as that described by Adams.

SUMMARY

1. A careful study of the gait and erect posture should be made with the patient stripped.
2. A description of a number of characteristic limps is given.
3. Various test lines are described and their significance noted.
4. The Thomas and Trendelenburg signs are described with illustrations.
5. The value of Shenton's line is illustrated.

THROMBO-ANGIITIS OBLITERANS*

REPORT OF FIFTY-TWO CASES

Alexander G. Dumas, M.D.
Neuro-Psychiatric Consultant, U. S. Veterans' Hospital,
and
Edward T. Evans, M.D., F.A.C.S.
Attending Orthopedist, U. S. Veterans' Hospital,
Minneapolis

A DISEASE of apparently increasing frequency, at least in its early recognition, and most insidious in onset, accompanied by varied manifestations which, in the early stages, tax to the utmost the diagnostic ability of the physician.

For various reasons we have for some time felt that it would be appropriate to informally discuss this disease and elucidate certain points which should aid in an early diagnosis.

After observation of individual cases over a period of years, both in the hospital and in the out-patient clinic at this station, we were impressed that too often the diagnosis is not considered in ailments of the extremities.

We have been impressed with the gradual development of the disease in the individual cases. As a result of our study of these in retrospect we feel that we can draw certain conclusions on subjective symptoms and objective findings in the early case.

Spontaneous gangrene of the extremities has been noted for years, as have also other less serious circulatory changes, but not with any clear understanding. Quesnay, in 1739, mentioned possible occlusion of the artery causing gangrene. Raynaud, in 1862, published his thesis "Local Asphyxia and Symmetrical Gangrene of the Extremities." Intermittent claudication was recognized. Von Winiwarter, in 1879, reported the first recognizable case and termed it endarteritis and endophlebitis. Since then, numerous cases have been reported, but it is difficult to determine the pathological classification in many. It remained for Buerger, in 1908, to elucidate the pathology, and his criteria stand today as the basis for positive diagnosis. Since then, interest in the condition has steadily advanced, and many cases are reported, with suggestions as to etiology, diagnosis and treatment.

---

*Read before a joint meeting of the Hennepin and Ramsey County Medical Societies on October 30, 1929.

Brown, Allen and Mahorner have recently reviewed the subject most thoroughly.

The interest of one of the authors in the subject began in 1922, when he reviewed a series of amputations performed for this condition at the Boston City Hospital. To his surprise, he found that more than sixty per cent were of Irish extraction. As he looks back, he recalls that the diagnosis was made in the presence of gangrene and from pathological studies, and that early diagnosis was most rare.

That this state of affairs still exists cannot be denied. Many cases still go undiagnosed until major symptoms appear.

The opportunities afforded us to study the disease at this Clinic have been unusual, and we feel that a report, considering various means of diagnosis, is warranted at this time.

ETIOLOGY

The numerous suggestions as to etiology are evidence that as yet no single factor can be termed causative. It is, however, probable that infection is responsible. Rabinowitz claims to have isolated an organism which reproduced the lesion in rabbits, but his work has not been confirmed. English observers report the presence of a histamine-like substance in tissues, activated under certain barometric conditions, causing local changes similar to those in Raynaud's disease, and, if extensive, simulating endarteritis in its local end-stages. Typhus is mentioned. Only one of our cases had an indefinite history of this disease. Males are affected with only very rare exceptions. The use of tobacco and ergot have been discarded as anything but possible predisposing or aggravating factors. Buerger does not feel that exposure to wet or cold is a cause *per se,* but rather is an exciting factor predisposing to gangrene. We feel that foci of infection may play a part if local factors are favorable for the development of the disease.

PATHOLOGY

The pathology is not an endarteritis, but an occluding thrombosis affecting arteries and veins. This occlusion occurs usually in the deep vessels, but often is present in the superficial veins.

GROSS PATHOLOGY

The deep vessels of the amputated legs regularly show an extensive obliteration of the larger arteries and veins. Besides this, there are two lesions which vary greatly in their intensity—periarteritis, and, not infrequently, arteriosclerosis. The appearance of the vessels on gross section depends upon the age of the occluding process. Usually the vessel is seen to be filled with a grayish or yellowish mass that can be distinctly differentiated from the wall of the vessel, and that appears to be pierced at one or a number of points by an extremely fine opening through which a minute drop of blood can be squeezed. Such obturating tissue is firm in consistency, and does not at all resemble the crescentic or semilunar occluding masses typical of arteriosclerosis. The vessel itself is usually contracted, so that its wall appears somewhat thickened. This picture is characteristic of arteries or veins which are the seat of a very old obliterative process and is to be found most frequently in the peripheral portions of the vessels, although at times this type of lesion may extend throughout the whole length of the vessel, from the dorsalis hallucis into the popliteal artery.

The veins share equally with the arteries in the lesion of occlusion. In some cases they are more extensively involved than the arteries; this is particularly true of the collaterals of the posterior tibial, which are often closed when the anterior tibial veins are open. As for the arteries, we usually find an obliteration of a part or the whole of the anterior tibial, of the dorsalis pedis and of the dorsalis hallucis, an occlusion of the posterior tibial and plantar vessels, with or without involvement of the peroneal.

Besides the lesion of occlusion, there are two other striking changes, namely, a certain amount of arteriosclerotic thickening and periarteritis. Arteriosclerosis is absent in the younger cases; when present, it is never pronounced, except in those rare instances in which the patient has suffered from the disease for many years, and has reached the age of forty or over. As a rule, we note but very slight degree of whitening or thickening of the intima, here and there in the patent portions of the vessels. In a very few cases small atheromatous patches are present.

A much more interesting and more important change is the fibrotic thickening of tissues immediately about the vessels. Wherever the vessels are occluded, there is apt to be an agglutinative process which binds together the artery and its collateral veins and sometimes, also, the accompanying nerve, so that liberation of the individual vessel by dissection is difficult. The adhesive condition is due to fibrous tissue growth, and varies considerably in its amount. The periarterial fibrosis varies, sometimes being almost absent, at other times so great that isolation of the vessels or nerves becomes impossible and the vascular structures make up one dense rigid cord.

HISTOPATHOLOGY

The lesions may be considered in two stages: first, the healed or organized stage; second, the acute or incipient stage of thrombosis. Between the earliest alterations in the deep arteries and veins and superficial veins, and the final stage of the disease, there are a large number of intermediate pictures that illustrate the metamorphosis of the obturating clot into the intravascular cicatrix.

1. *Healed or Organized Stage.*—The most common lesion is a total obliteration of the lumina of arteries and veins by connective tissue. Histologically this may be extremely varied in the general appearance, but each picture can be interpreted correctly as having its origin in the lesion of occlusive thrombosis. This obturating connective tissue usually harbors numerous small vessels, pigment containing hemosiderin, and a fair amount of connective-tissue cells. The canalizing vessels, when they became dilated, form smaller or larger sinuses, giving the fenestrated or cribriform lesion seen on microscopic section of the vessels, or *when the canalizing vessel becomes eccentrically placed and sufficiently large, this sinus is responsible for the appearances which have been incorrectly interpreted as the product of an endarteritis obliterans.*

Elastic tissue stains demonstrate characteristic differences between this process and that of arteriosclerosis. Thus, the region of the organized clot is almost completely free from elastic tissue. The small amount which is present is concentrically disposed about the new formed vessels. The abundant elastic tissue formation in the arteriosclerotic plaques is well seen. A combination of thrombo-angiitis obliterans and arteriosclerosis is shown in some cases.

Still more suggestive and instructive is the finding of various stages of the disease in different members of the same vessel sheath. Thus, a large artery affords a view of the old lesion as well as one of its venæ comites. Another accompanying vein is in the "acute" stage of the disease, a smaller venule or satellite being in the intermediary stage, where certain "miliary giant-cell foci" make their appearance. Such pictures not only reveal the thrombotic nature of the disease, but also present an argument in favor of the following two assumptions: *that the disease begins with an inflammatory lesion attended with occlusive thrombosis, and that it affects the arteries and veins in a sort of relapsing fashion, very much in the same manner as the veins in migrating phlebitis.*

The termination of the occluding tissue in arteries and veins is often seen in the form of a rounded, convex projection looking upward (cephalad), and lying in seemingly healthy vessel wall. At other times, the old occluding tissue is capped by an additional clot rising in pyramidal fashion, ending by a long tapering extremity.

2. *The Acute or Specific Lesion.*—The early lesions are so characteristic histologically that their appearances are distinctly specific for thrombo-angiitis obliterans and perimt the pathologist to make a diagnosis of the disease. They are rarely to be seen in the deep vessels for the reason that patients do not allow amputation until the disease has lasted for months or years. However, they can be well studied when these are the seat of the typical migrating phlebitis, which has been shown by Buerger to be identical with the acute lesions in the deep vessels.

The earliest changes appear to be the usual evidences of an acute inflammatory process involving all the coats of the vessel. The media, adventitia, and perivascular tissues are infiltrated with polynuclear leukocytes, and the lumen of the vessel is completely filled with red clot. In the peripheral portions of the clot, large or small foci of leukocytes (purulent foci) begin to form, whose growth occurs by virtue of immigration of leukocytes. Certain peculiar and characteristic giant-cell foci then develop. They contain giant cells, endothelioid cells or angioblasts and numerous broken-down leukocytes. These foci then undergo connective-tissue replacement. The giant cells gradually disappear, numerous small vessels are formed, the final product being fibrous tissue containing vessels and some pigment. In the rest of the occluding clot the organizing process is somewhat different, resembling that which characterizes the organization of blood-clot in other thromboses.

In short, the lesions in thrombo-angiitis obliterans are, in chronological order: an acute inflammatory lesion with occlusive thrombosis, the formation of miliary giant-cell foci, the organization and canalization of the clot, the disappearance of the inflammatory products, and the development of fibrotic tissue in the adventitia that binds together the artery, vein and nerves.

(*Note.*—Much of the above description of the pathology has been drawn verbatim from Buerger's monograph.)

DIFFERENTIAL DIAGNOSIS

Before discussing the differential diagnosis in circulatory disturbances of the extremities, we feel that a few words relative to the reason why the neuro-psychiatrist should be interested in this subject might not be out of place.

The United States Veterans' Administration has classified the angioneuroses, for compensation purposes, under neuropsychiatric disabilities, and, therefore, all cases presenting symptoms that might point to these conditions are referred to the Neurological Section. These include Raynaud's disease, erythromelalgia, trench feet, angioneurotic edema, acroparethesia, multiple neurotic gangrene, scleroderma, sclerodactylia, chronic acro-asphyxia, and familial gangrene.

In addition to these conditions, many of the organic neurological diseases, especially those involving the spinal cord, have circulatory symptoms. In cases of recent total transverse lesions of the spinal cord the lower limbs are usually abnormally warm, the greatest change occurring distally. This is due to vasomotor paralysis. Erythromelalgia is sometimes one of the earliest signs of organic cord disease, such as disseminated sclerosis, and this points to its origin from an affection of the spinal vasomotor centers, probably the nucleus sympatheticus lateralis between the anterior and posterior horns. Again, many patients with circulatory disease present early symptoms simulating neuritis and neuralgia. In addition, there may be traumatized or severed peripheral nerves, with ulceration, such as is represented in one case in our series, where the sciatic nerve was severed by a gunshot wound. Circulatory disturbances are common in peripheral nerve injuries, and frequently an artery is injured at the same time as a nerve.

Since thrombo-angiitis obliterans represents the largest disease entity in our group of circulatory disturbances, it must be differentiated from the other circulatory conditions. The conditions to be differentiated are placed in two large groups:

1. Organic vascular diseases of the extremities.
2. Cases of neuropathic or neurogenic vascular disorders.

Under the heading "Organic vascular diseases of the extremities" must be considered diabetic gangrene, arteriosclerosis, aneurysm, embolic or thrombotic gangrene, luetic endarteritis, peripheral nerve injuries, with or without blood vessel injury. In addition to these organic vascular diseases there are a few other diseases that have symptoms that occur in thrombo-angiitis obliterans, namely: myositis, metatarsalgia, neuritis, neuralgia, various cord diseases, pes planus, pes cavus and thrombo-phlebitis. Practically all of these conditions have claudication as a symptom.

The neuropathic or neurogenic disorders to be differentiated are: Raynaud's disease, erythromelalgia, trench feet, angioneurotic edema, multiple neurotic gangrene, scleroderma, sclerodactylia, chronic acro-asphyxia, familial gangrene.

For the clinical diagnosis of thrombo-angiitis obliterans, we must depend upon:

1. Sex—male predilection.
2. Early involvement of the lower extremities.
3. Early symptoms of claudication or pain.
4. Migrating phlebitis.
5. Pulseless vessels.
6. Blanching of the extremities in elevated positions (angle of circulatory efficiency).
7. Rubor in dependent position.
8. Relation of hyperemia phenomena to posture.
9. Slow process, chronic course, keeping in mind that some cases have spontaneous arrest.
10. Absence of simultaneous symmetrical involvement.

Diabetic gangrene is differentiated by the presence of sugar in the urine, hyperglycemia, and other associated signs of diabetes, with gangrene.

Arteriosclerosis is determined by the age of the patient and the condition of the blood vessels in general and evidence of generalized arterial disease not limited to the periphery.

Aneurysm presents a bruit and a history of syphilis or trauma with findings for the same. Serological study is of value here.

Embolic or thrombotic gangrene is associated with a history of infection or heart disease, with sudden onset for the former and a gradual onset from infected foci for the latter.

Luetic endarteritis: serology and associated manifestations of syphilis.

Peripheral nerve injuries with circulatory disturbances are differentiated by presence of motor paralysis or loss of sensation following an injury.

The associated conditions, such as myositis, metatarsalgia, neuritis, pes planus and pes cavus, are differentiated on the basis of symptoms characteristic of these conditions. The most difficult differentiation is in neuritis, especially in the irritative stage, as many of the endarteritis cases have extreme tenderness over the nerve trunks, especially in the distal portions of the extremities, and before occlusion of arteries occurs many of these cases are wrongly diagnosed neuritic.

Any type of foot strain can cause claudication, and this symptom is one that gives considerable trouble in differential diagnosis.

In differentiating thrombo-angiitis obliterans from the angioneuroses, the following points may be of assistance:

Raynaud's disease. The mildest degree of this is local pallor ("local syncope" or "dead finger"), where the affected parts, usually the fingers, less frequently the toes, the edges of the ears, or the tip of the nose, suddenly become cold to the touch and of a waxy white color. Together with this, the patient feels a tingling or peculiar sensation (acroparesthesia). Actual blunting of sensation to touch may be present. One or both hands may be affected, sometimes identical fingers in both hands; the thumb is less often affected than the other digits. The attacks last from a few minutes to several hours and are commonest in winter. They are often brought on by washing the hands in cold water, or by fine digital movements such as in sewing or piano-playing. As the attack passes off, the patient feels a sensation of tingling or even of pain. A more severe variety is that of local asphyxia or cyanosis, in which the affected digits suddenly become discolored, varying in tint from a dusky blue or slate color to an intense purplish-black. Pressure on the discolored area causes a white mark which persists for several seconds, before the lividity slowly reappears. The pain is usually more intense than in local syncope. As the attack passes off, the affected part often sweats freely. But the most severe variety of Raynaud's disease is symmetrical gangrene, which is usually preceded by local asphyxia and sometimes by local syncope. As a rule, the gangrenous process is confined to a small part of the cyanosed area. In its mildest form the necrosis is limited to the epithelium, so that only desquamation results. More often a small blister forms, with blood stained contents. This bursts, leaving an ulcer with subsequent scar tissue. The nails may be lost temporarily, or the necrosis may extend deep into the tissues, forming a dark slough. Whole phalanges may undergo dry mummification and be cast off, leaving a conical stump, with the bones escaping early necrosis. Pain is usually severe during the initial cyanosis.

The symptoms of Raynaud's disease are due to local spasm of the vessels, their sudden onset and disappearance being incompatible with any other hypothesis. The coexistent sensory symptoms are probably due to imperfect blood-supply. A paroxysm of local syncope or cyanosis can usually be relieved, as Cushing has pointed out, by applying a tight flat rubber tourniquet around the limb above, so as to occlude all the vessels, both arteries and veins, and leaving it on for several minutes. When the tourniquet is taken off, there is a temporary vasomotor paralysis, the whole limb flushes to the finger tips, and a wave of redness wipes out the local pallor or cyanosis. In rare cases paroxysmal impairment of vision has been noted, and during such attacks the retinal arteries on ophthalmoscopic examination have been seen to be spasmodically contracted. In paroxysmal hemoglobinuria, Raynaud's syndrome is constantly present, to a greater or less degree.

In striking contrast with Raynaud's disease is the condition known as erythromelalgia, which usually attacks one or the other foot. There is pain of a burning or stabbing character, often of excruciating severity, occurring in paroxysms, lasting from a few minutes to several hours. This pain is always aggravated by dependent posture of the limb, by voluntary movement, or by warmth, whereas it is diminished by a horizontal or elevated posture, by rest, and by cold applications. The earliest attacks consist simply of pain. As the disease progresses, however, redness and swelling of the foot occur in addition; more rarely, redness precedes pain. The redness is of a bright tint, often confined, for instance, to the ball of the big toe or to small areas of the sole or edge of the foot. Sometimes it is diffused over the foot. The redness increases in intensity, and if the limb be allowed to hang down, the "vascular storm" continues, with bounding arteries, local rise of temperature and intense cutaneous hyperesthesia. As the attack subsides the redness is replaced by cyanosis.

There are other cases in which the vasomotor symptoms are intermediate in type between the two extremes of Raynaud's disease and erythromelalgia. These two diseases may coexist, or may succeed each other in the same patient.

Among soldiers defending sodden trenches in the winter season, as in the World War, there occurred numerous cases of trench-foot. Very few of the cases, however, were due to actual frost. True frost-bite, which is usually the result of intense dry cold, is characterized by suddent, massive tissue-death of the tip of an extremity, whereas trench-foot has a progressive invasion of the tissues, and when it shows gangrene does so in circumscribed patches. The factors producing trench-foot are prolonged exposure of the feet to cold, muck, and thawing snow, want of exercise of the leg muscles, together with prolonged constriction by tight putties and boots which undergo shrinkage when soaked. The signs are primarily vascular in origin, to which may be superadded the sensory phenomena of a peripheral neuritis. The toes become cold and pale, in some cases cyanosed and in rarer cases gangrenous. There is slight impairment of cutaneous sensation in the toes, with considerable pain and tingling. At the outset the peripheral arteries of the feet are tightly contracted, and there is a local rise of blood pressure in the legs, which can be measured with a manometer. The vascular spasm produces local ischemia, with numbness and pain. When the surrounding atmospheric temperature rises, the vessel-walls become relaxed and even paralyzed, so that vascular dilation occurs, with exudation of serum into the tissues through the damaged capillary walls. Thus edema of the feet may supervene, and in severe cases is associated with excoriation and secondary infection of the skin. This edema may extend up to the knees. As the circulation begins to return, the pain becomes aggravated, and even after the circulatory phenomena have apparently recovered, pain may persist, with characteristic signs of peripheral neuritis. This is shown by the combination of impairment of sensation to light touch together with intense hyperesthesia on pressure, so that for weeks the patient may be unable to stand or walk, owing to pain in the soles of the feet, especially anteriorly.

Angio-neurotic edema is differentiated by paroxysmal attacks, lasting a few hours, of sharply defined, localized, hard edema, occurring in the cellular tissues of the face, lips, eyelids, trunk or limbs. The swelling is firm, does not pit on pressure, passes off spontaneously or after the sub-cutaneous injection of adrenalin. It may attack the mucous membranes of the respiratory tract.

Multiple neurotic gangrene of the skin is a dermal process in which vasomotor constriction is not limited solely to the extremities, but to isolated patches of skin. It occurs in hysteria and schizophrenia. The disorder sets in with burning and prickling sensations of the skin and then, after a variable length of time, a few minutes to hours, swelling occurs, and blisters form; later necrosis. At times only a circumscribed edematous bleb occurs.

Scleroderma is a progressive induration of the skin occurring in circumscribed patches. The skin is hard and pigmented. Destructive changes may occur even resulting in periarticular immobilization of joints.

Sclerodactylia, a disease of fingers or toes, allied to scleroderma, occurs in women, and leads to deformity.

Acro-asphyxia is an asphyxia of the extremities of a chronic nature, without other involvement.

Familial gangrene resembles Raynaud's disease somewhat, and the following description by Purves Stewart is classical:

> "Three brothers, aged five, four and three years, respectively, in all of whom, one winter, there developed local necrosis of the feet. The oldest child had necrosis of the skin of both heels, followed by similar areas on the dorsum of the right foot and on the fourth left toe. The second child had cyanosis and some necrosis of the dorsal surfaces of both feet, whilst the youngest had severe necrosis of the dorsal surfaces of both feet, of the hallux, fourth and fifth toes on the right side, and a smaller area of necrosis on the plantar surface of the left hallux."

In working up our group of cases we have used a modification of the data sheet proposed by the Mayo Clinic and the cases have been reviewed under the following headings: Name, age, sex, nationality and birthplace, family history of vascular disease, smoking habits, past diseases, precipitating factors and claudication,—location and severity of rest pain and how it is relieved, the presence or absence of color changes followed by a summary of progression, including vasomotor disturbances whether local or general, whether accompanied by phlebitis, thrombosis, ulcers or gangrene. Prior treatment, prior diagnosis and a chronological history of surgical procedures were noted.

The following diagnostic points were stressed in our examinations: Palpation of the main arteries of the legs and arms, graded on the basis of four. The observation of dependent rubor, elevated pallor and edema was made and noted. Gangrene, if present, was, of course, noted. Attempts were made to produce claudication and rest pain. In some cases hot and cold water tests were used. The temperature of the extremities was noted as compared with the normal skin temperature. In all cases recently under our observation we have used a test which we have termed the Allen Test in which (after a blanching has been produced in the elevated position) and one or the other of the large vessels to the extremity is blocked off by digital pressure, the extremity is lowered and an observation of the collateral circulation is made.

Every patient had routine physical and laboratory examinations and such special examinations as seemed indicated.

A review of the pathological files of the hospital, including the out-patient clinical material for the past ten years, shows sixty-three cases of circulatory disturbance in the extremities, of which fifty-two have been classified as thromboangiitis or endarteritis obliterans. We have not included in this list any cases of frank arteriosclerosis or luetic endarteritis, although there are some of the cases diagnosed endarteritis which have been placed in discard because of the possible presence of more obvious conditions. These cases constitute eleven which are diagnosed as follows:

Raynaud's—2.
Epidermophyton—1.
Diabetic Arteriosclerosis—3.
Trench Frostbite with a Healed Amputation—1.
Circinoid Aneurism of the Radial Artery Followed by Amputation—1.
Arteriosclerosis with Diagnosis of Thromboangiitis Obliterans—2.
Sciatic Nerve Injury with Ulcer and Amputation—1.

A brief summary of the remaining 52 cases follows:

Ages at onset range from 19 to 38 years with one case each of 51 and 60 years of age. Duration of disease ranges from two to twelve years (average duration eight years and nine months).

Nationalty:	Jewish	14
	Celtic	20
	German	8
	Scandinavian	6
	Latin	3
	Undetermined	1
		—
		52

POSSIBLE ETIOLOGICAL FACTORS

Exposure in service, foot and leg strain	4
Trench warfare associated with severe exposure to the elements	22
Cold	6
No service exposure	14
Dental caries	19
Rheumatic infections of various types	13
Nose and throat infections	14
Pulmonary infections, including tuberculosis	12
Prostatitis	9
Amebiasis and other gastro-intestinal infections	10
Typhoid	2
Hypertension	1
Acoholism	1

Positive blood Wassermanns were found in five cases, in four of which, despite progression of endarteritis symptoms, all serological tests were negative for the past year after intensive treatment.

As evidence of the difficulty in diagnosing these conditions, which difficulty was pointed out earlier in this paper, it is interesting to review some of the earlier diagnoses which these cases carried:

Pes planus	19
Circulatory disturbances	8
Metatarsalgia	8
Varicose veins	3
Rheumatism	7
Neuritis	5
Raynaud's disease	6
Myositis	1
Trench feet	5
Acrocyanosis	1
Luetic endarteritis	3
Tuberculosis of the bone	1

The type of progression in these cases is interesting from a standpoint of prognosis.

Forty of the series could be classified as slow progression, two as sudden and ten as recurrent with severe manifestations. Thirty-nine cases presented a history of claudication classified as: none mild, twenty-two moderate, and eight severe. Rest pain was present in thirty-four cases. Easy fatigue was present in forty-two cases. Color changes were present in forty-one cases. Thrombosis of the main arteries was present in fourteen cases, not all of which required surgical interference, and phlebitis was present in twelve cases. Gangrene was present in seventeen cases, classified as: Ulcers—7; moderate gangrene, that is, of the toes—5; severe gangrene—5.

Simple amputations were done in two cases and repeated amputations were done in twelve cases. Two cases had peri-arterial sympathectomy, one followed by amputation later; the other done a year ago and not traced. Three cases are included in this series on an old diagnosis on which we have no recent data. Two have had ganglionectomy with some relief of pain. All cases with mild and moderate symptoms have had various forms of physiotherapy and repeated courses of intravenous typhoid vaccine. What do the above facts indicate, but that the condition is being recognized early, that it is much more insidious and slower than usually thought to be, and that conservative measures have proven of some palliation in those cases of slow progression?

Whereas, many of our patients have been given treatment of various kinds, notably the relief of abnormal static demands by orthopedic measures, physiotherapy, Bier's hyperemia, and postural exercise, the clinic facilities, until recently, were such that typhoid therapy and tests of the vasomotor index could not be done routinely. These are finer methods occasionally necessary for diagnosis and the evaluation of cases suitable for lumbar sympathectomy.

CONCLUSIONS

1. The differential diagnosis of circulatory disturbances of the extremities calls for most careful examination and evaluation of findings.

2. Thrombo-angiitis obliterans can and should be recognized early.

3. Our series demonstrates no specific etiology, but strongly suggests lowered local resistance following exposure, with superimposed infection.

4. There are at present no criteria on which prognosis can be based. Most cases are slowly progressive, but may be subject to sudden severe flareups.

5. Treatment of the mild cases should be palliative. Surgery offers the only relief in severe cases.

6. No conclusions are made regarding foreign protein therapy, except that it offers temporary palliation.

SKIN TESTS IN CHRONIC ULCERATIVE COLITIS*

J. C. Thomas Rogers, M.D., and J. Arnold Bargen, M.D.,
Rochester, Minnesota

THE value of intradermal injections in the study of certain infectious diseases has been generally accepted. Rosenow has suggested the importance of skin tests in various infectious diseases.

Local reactions from such procedures have been noted to vary as individual resistance has changed, either from active or passive causes, or in accordance with a person's native immunity to infection. The work of the Dicks excellently illustrated this feature.

Since the early studies of Koch and von Pirquet, cutaneous reactions in tuberculosis have become common knowledge. Here is, in addition to the phenomenon of immunity, the often superimposed one of allergy. Because of the intimacy with which the two are associated in this particular instance, there is a general tendency to think of the two conditions as synonymous. However, this is not a true conception, as has been definitely proved by Rich and his collaborators. He stated "acute inflammation is a protective mechanism, but it does not follow that an enhanced capacity for reacting with inflammation (allergy) is always necessary for protection."

Dorst and Morris for several years have been interested in skin tests and their use in explaining the clinical pictures of spastic or irritable colon and mucous colitis on the basis of hypersensitivity of the enteric tract to certain bacteria. They have noted very encouraging results from desensitization with autogenous vaccines made from cultures of organisms which were obtained from the stool, and which gave positive allergic skin reactions.

Anaphylaxis may be present in the development of immunity in infectious disease, but not necessarily so. Yessner has shown that in experimental sporotrichosis allergy develops, but rapidly disappears, and that the animal then enjoys perfect acquired immunity.

It is not within the scope of this study to attempt to determine the relationship of allergy to immunity. Our particular interest lies in the problem of immunity in chronic ulcerative colitis, and although hypersensitivity at times has been an early, more or less prominent factor, results of skin tests applied to persons afflicted with this disease have been such that certain deductions have been warranted.

The antigens used for the intradermal injections were prepared by Rosenow, and represented a suspension of 200,000,000 organisms for each cubic centimeter of physiologic sodium chloride solution, preserved with 0.2 per cent phenol. As many as fifteen different antigens were injected into a single patient, but the antigens in which we were particularly interested were those of the diplostreptococcus of chronic ulcerative colitis and two other organisms found in cultures of material from the rectum and sigmoid; namely, Streptococcus fæcalis, and enterococcus. The last two were included because of their similarity to organisms of chronic ulcerative colitis. The three organisms, although similar, exhibit strikingly different characteristics. Not only do they have different cultural characteristics, but, as Zozaya has demonstrated, from each a specific polysaccharide can be isolated.

The injections of 0.05 c.c. of each antigen were made intradermally, on the volar surface of the forearm, and readings were made at various intervals following injection, but the most satisfactory interval was found to be twenty-four hours. Rarely did a typical allergic reaction occur, and when present was noted within thirty minutes after injection of the antigen.

---

*Dr. J. C. Thomas Rogers, Fellow in Surgery, The Mayo Foundation, and Dr. J. Arnold Bargen, Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the Central Society for Clinical Research, Chicago, Illinois, November 22, 1931.

Absence of, or merely slight, redness surrounding the needle puncture was recorded as negative. The reactions were graded. Redness, and a variable but usually slight swelling, limited to the blistered area, up to 0.5 cm. in diameter, was graded 1; a reaction from 0.5 to 1 cm. in diameter was graded 2; a reaction from 1 to 2 cm. in diameter was graded 3, and a reaction 2 cm. or more in diameter was graded 4 (Fig. 1).

In the course of three months, fifty-seven patients who had the clinical and laboratory manifestations of chronic ulcerative colitis were given injections. Seven of these patients were in the second decade of life; twenty in the third; fifteen in the fourth; eight in the fifth and five in the sixth or a later decade. In accordance with the figures of others, and our own, the ages at which the disease is most prevalent are between twenty and forty years. In this group there was no attempt whatever at selection of cases because of any clinical factors of age, sex, or laboratory findings other than those consistent with correct diagnosis. For example, patients who had as many as twenty bloody rectal discharges daily, anemia (hemoglobin as low as 22 per cent), and symptoms for as long as seventeen years were observed in turn, just as those who had only three or four stools daily, no demonstrable anemia, and a year or less of trouble. There were thirty-two males and twenty-five females.

As many patients as possible were tested before treatment with antibody globulin solution. In this treatment, the initial dose of 0.1 c.c. was increased by 0.2 c.c. daily until the usual maximal amount of 3 c.c. for each injection was attained. Occasionally, the local and general reactions of the patients required some modification of this routine, making it necessary to proceed more slowly. Skin tests were again made after a series of such injections, frequently at the time of dismissal.

For comparison, ten healthy persons between the ages of twenty and fifty years were tested. The diplostreptococcus of chronic ulcerative colitis, the Streptococcus fæcalis and the enterococcus, in the usual concentrations, were used as antigens. A control of 0.2 per cent phenol in sodium chloride solution was used in each instance. The reactions were graded as follows: in two cases, grade 2; in five cases, grade 3, and in three cases, grade 4.

All patients who had chronic ulcerative colitis, with the exception of seven, exhibited local skin reactions, of varying intensity, to the diplostreptococcus of chronic ulcerative colitis, or to Streptococcus fæcalis, or to the enterococcus or to all. The seven patients were those who gave no local reactions whatever to the antigens mentioned, and will be referred to later. The skin reactions of the remaining forty-nine patients were not constantly commensurate with the gravity of the disease. Such factors as anemia, number of stools, fever, duration of disease, or remote previous treatment showed no constant tendencies to modify the reactions in any way.

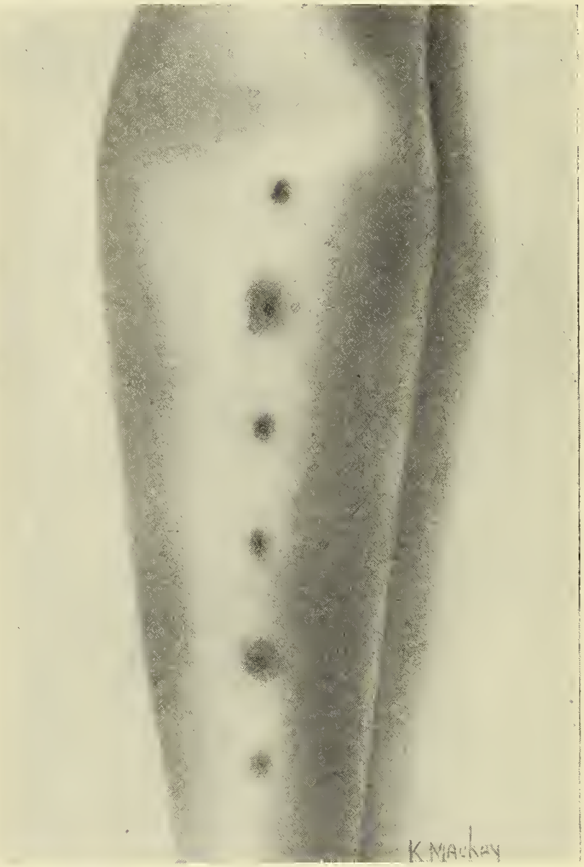

Fig. 1. The size and extent of the wheal after intradermal injection of the organism to which the patient was sensitive.

It was possible to follow the twelve cases noted in the table more closely than the others.

Of these twelve cases, in every instance in which the skin tests were negative following treatment, after there had been a positive reaction before treatment, there was unquestionably definite and marked improvement in the patient's condition. The intensity of the preliminary test gave no indication of the possibility of later negative reactions.

RESULTS OF TREATMENT WITH ANTIBODY GLOBULIN SOLUTION

Case	Reaction before treatment, grade	Duration of treatment, days	Reaction after treatment, grade	Hospitalized	Stools, daily	Hemoglobin, per cent	Duration of disease, years	Progress
1	1	42	0	No	6 to 8	65	4	Clinical cure
2	3	30	0	Yes	7 to 8	60	3	Clinical cure
3	2	72	2	Yes	7 to 10	47	1.5	No improvement
4	2	24	1	No		64	4	Improved
5	2	11	0	No	20 or more	72	5	Clinical cure
6	2	48	0	Yes	20	22	2.5	Clinical cure
7	3	17	0	No	6 or more	56	3	Markedly improved
8	2	28	0	No	6 to 8	77	8	Markedly improved
9	0	33	2*	Yes	4 to 6	54	3	Markedly improved
10	1	25	0	No	10 to 12	81	13	Markedly improved
11	4	21	4	No	5 to 6	76	1.5	No improvement
12	3	27	2	Yes	15 to 20	44	8	Flare-up with tonsillectomy at second test; doing well up to that time

*Test made on patient's return, after seventy-nine days at home, during which time he had mild exacerbation of his trouble associated with perirectal abscess.

If, after a course of treatment usually adequate for good results, the skin tests remained positive to a degree similar to that before treatment, there was little if any clinical improvement. Cases 3, 11 and 12 illustrate this. In case 3, antibody globulin solution and some vaccine were given over a period of seventy-two days, without there being appreciable change in the clinical condition, and with no change in the cutaneous reaction. The interesting feature about Case 12 was that the patient began to show encouraging signs of improvement for three weeks after entrance to the clinic, and until she underwent tonsillectomy. This episode caused a severe flare-up of the colitis and at the same time the skin tests became positive, but with less intensity of reaction than formerly. Cultures from this patient's tonsils reproduced most severe ulcerative colitis in rabbits. In Case 11 there were marked initial reactions, graded 4; treatment for three weeks caused no change in clinical condition or skin tests. Recent correspondence with this patient disclosed that she was continuing to do poorly.

The patient in Case 9 did very well on his first visit to the clinic. His skin tests were negative before he received any serum whatever. But after an absence of seventy-nine days, he returned with an exacerbation of the old condition, probably incited by a local infection about the anus. At this later time, skin tests were definitely positive, graded 2.

The number of days of treatment between the original skin tests and the second tests varied (table). In Case 5 there was unusual improvement in eleven days, at which time skin tests were negative. On the other hand, in Case 6, forty-eight days of treatment were required before clinical cure supervened.

It is possible that the skin tests in many instances were actually negative long before a second test was done. Instead of doing frequent tests on these patients as treatment continued, and possibly stopping administration of antibody globulin solution as soon as the tests became negative, we did our second tests when the patient had made definite improvement or had shown little if any tendency toward betterment.

Of the original fifty-six cases, the initial cutaneous reactions were negative in seven. The first of these patients had had full doses of antibody globulin solution for four weeks before the initial test; the condition was excellent at the time of the test. The second patient had had full doses of antibody globulin solution for four weeks before the tests; the condition was improved markedly at the time of the tests. The third patient had had no treatment with antibody globulin solution, but had had three years' rest in bed;

the condition in the bowel was well localized. The fourth patient had received antibody globulin solution and vaccine on previous visits to the clinic, and returned merely for re-examination, in very good condition. The fifth patient had received vaccine elsewhere, and, although markedly improved, came to the clinic for evaluation of the condition; the general condition was very good. The sixth patient had received antibody globulin solution on previous visits and vaccine at home; the condition was very good. The seventh patient had received antibody globulin solution and vaccine previously, with excellent results.

The third patient is represented as Case 9 in the table.

The clinician finds it difficult to evaluate individual resistance to the infection in chronic ulcerative colitis. The mental attitude of the patient is capable of markedly changing the picture. Now, if it is possible to estimate by a series of innocuous skin tests how the case is progressing, an important step in the standardization of the treatment of chronic ulcerative colitis has been taken.

It is easily seen (table) that the tests become negative in some cases sooner than in others. In other words, there is undoubtedly individual variation in the protective qualities, and the amount of antibody globulin solution necessary to bring about general clinical improvement in one case may be entirely inadequate in another. The question naturally arises as to the feasibility of controlling the amount of antibody globulin solution to be given, by means of skin reactions.

This study furnishes additional data supporting our contention that the disease is of specific etiology. If a substance such as the antibody globulin solution is introduced in the treatment of these patients, and there is consequent complete negation of skin reactions, the substance appears to be a specific agent. Administration of this antibody globulin solution seemingly has been the chief factor in effecting increased resistance and clinical betterment in the cases observed. It is to be hoped that this study may lead to a more definite prediction of the length of time over which a patient should receive specific treatment.

In two cases, now to be reported, the effect of treatment and the results of skin tests were as nearly opposite as could be.

Case 1.—A married man, aged twenty-eight years, had had no intestinal trouble of any kind until May, 1924, when he had diarrhea of rather sudden onset. At first there were only two to three loose stools daily, with occasional streaks of blood. The number of stools increased in frequency until, at the time he entered the clinic in August, 1930, he had five to eight soft, bloody discharges daily. Between the time of onset and August, 1930, more than seven years, many forms of treatment, including a vaccine made from organisms cultured from his stools, had been tried without beneficial results.

The patient was fairly well nourished, and was able to be up and about. Physical examination was negative except that a tender, rope-like mass was palpable in the left lower abdominal quadrant. The mucosa of the rectum and sigmoid was glazed and granular. Bleeding occurred with slight trauma. The lumen had become contracted, losing about a third of its usual diameter. The concentration of hemoglobin was 60 per cent, erythrocytes numbered 4,220,000, and leukocytes 7,600 in each cubic millimeter of blood. Diplostreptococci of ulcerative colitis were isolated from cultures of the rectal mucosa, and the roentgen diagnosis was chronic ulcerative colitis involving the entire colon, apparently active. In spite of these observations, the patient decided to go home without treatment. At home he continued to have five to six stools daily until a few months before he reëntered the clinic, when their number increased to about ten daily, and his ability to control them decreased.

May 25, 1931, the patient registered at the clinic again. At this time he was noticeably pale and weak, and showed evidence of recent loss of weight. May 27, 1931, he weighed 106 pounds. Antibody globulin solution, 0.1 c.c., was given intramuscularly. The amount of antibody globulin solution was increased by 0.2 c.c. daily until he was getting about 3 c.c. By June 12 his weight had increased to 113.5 pounds, the number of stools had decreased to as few as three in twenty-four hours, and his strength had increased remarkably. Intradermal tests were made before treatment was begun, and the reaction was graded 3. After thirty days of treatment the skin tests were all negative and the patient was ready to go home in very good condition.

In those cases in which treatment has accomplished little if anything, the skin tests have continued positive. To try to explain why the antibody globulin solution does not give complete relief to all is not within the scope of this paper. However, it is suggested that the ulceration and destruction present, irrespective of the infection, might account for any failure. If the skin tests continue positive after a thorough course of treatment, the question arises if improvement can come from prolonging the injections of antibody globulin solution. This study suggests a negative answer to this query. However, further observations and follow-up studies will be necessary before the answer can be definite.

Case 2.—A single man, aged twenty-two years, came under our observation May 25, 1931. In August, 1929, the patient first noticed blood and mucus in the stools; this continued for three days. A similar episode occurred in October, 1929. In February, 1930, he passed eight or more bloody stools daily. Since that time he had been miserable with abdominal cramps, weakness, and bloody rectal discharges. He was in the hospital five weeks, without improvement, before he came to the clinic.

There was a palpable, tender, cord-like mass in the lower left abdominal quadrant, which seemed to be the descending colon. On sigmoidoscopic examination, the mucosa of the rectum and sigmoid was granular, glazed, and bleeding. The lumen was contracted, so that about two-thirds of its normal diameter remained. Roentgenograms of the colon gave evidence of chronic ulcerative colitis involving the bowel distal to the hepatic flexure, with considerable shortening and narrowing. The concentration of hemoglobin was 47 per cent; erythrocytes numbered 4,170,000 and leukocytes 11,900 in each cubic millimeter of blood. The Wassermann reaction of the blood was negative. For seventy-two days the patient received the usual antibody globulin solution to the extent of his toleration. He was given most careful attention, and such adjuncts as blood transfusion, special diets, small amounts of vaccine, and preparations of iron compounds availed nothing in the way of improvement. At the end of this period of treatment this patient's skin tests were positive to the same degree as at the beginning.

The fact that in Case 9 (table) there originally was a negative skin reaction, and that the patient went home in good condition only to return seventy-nine days later, in trouble from ulcerative colitis, and with skin tests positive, allows an interesting speculation. If this patient makes progress clinically, we would expect the intracutaneous tests to become negative a second time. The controls demonstrated only that the average person gives a definitely positive skin reaction to the antigens.

SUMMARY AND CONCLUSIONS

We have studied the skin reactions of fifty-six patients with chronic ulcerative colitis after intradermal injections of antigens prepared from cultures of organisms isolated from the rectal mucosa of patients with the disease. The skin reactions of ten normal adults, using the same antigens, have been observed. As the condition of patients who had given positive skin tests improved, their skin tests became negative or decreased in intensity of reaction. This survey establishes the antibody globulin solution more strongly as a specific therapeutic agent in chronic ulcerative colitis. Employment of similar antigens for skin tests may give valuable aid in carrying on the treatment of patients with chronic ulcerative colitis.

OBSTRUCTIVE JAUNDICE FROM A SURGICAL STANDPOINT*

WALTMAN WALTERS, M.D.
Rochester, Minnesota

IN discussion of the treatment of patients with obstructive jaundice, of outstanding importance are the following points: The differential diagnosis between lesions within the liver and those without; the determination of the propitious time for operation; the correlation between the patient's symptoms and operative findings; the estimation of satisfactory postoperative progress, and finally the recognition of certain procedures of value in the treatment of postoperative complications.

DIFFERENTIAL DIAGNOSIS

From the standpoint of differential diagnosis, biliary colic followed by jaundice, with or without associated chills and fever, is indicative of intermittent obstruction to the passage of bile from the liver to the intestines. This is true whether the cause of the obstruction is stone in the common or hepatic ducts, tumor in the head of the pancreas, or stricture. When the jaundice is painless, the possibility of the lesion being intrahepatic must be considered. The distinction between intrahepatic obstruction and obstruction due to a tumor in the head of the pancreas in some cases is difficult. Broadly speaking, the appearance of jaundice without pain, affecting a patient whose stools contain bile, or from whom bile is obtained by duodenal tube, and whose gallbladder is not palpable or distended, is most likely to be the result of an intrahepatic lesion. Should the jaundice be constant and bile absent from duodenal content or stools, regardless of whether a distended gallbladder can be felt through the abdominal wall, the lesion is likely to be pancreatic.

In a study of patients operated on at the clinic for carcinoma of the head of the pancreas, producing obstructive jaundice, it was discovered that a distended gallbladder was palpated through the abdominal wall in only half of the cases. In a small group (approximately 5 per cent) a stone may exist in the common or hepatic bile duct, without causing pain. The corollary of this is that when the condition of the patient is such that abdominal exploration can be carried on with reasonable safety, the patient should be given the benefit of such a procedure. No one is infallible in the differential diagnosis of obstructive jaundice. The diagnosis is always so difficult, and the chance of saving a life so important, that, however positive the evidence of malignancy, operation is advised in all cases when the general condition permits.

PROPITIOUS TIME FOR OPERATION

In determining the propitious time for operation, an attempt should be made, in the preoperative diagnosis, to determine the situation of the lesion, for if the history is one of intermittent obstruction in which pain has played an important part, there is the possibility that the jaundice will decrease, making the patient a better operative risk.

The patient whose blood requires longer than nine minutes to coagulate constitutes an increased operative risk that is due not only to the tendency to bleed, but also to the probably more than usual injury to the hepatic cells. I have been of the opinion for some time that the relation of hepatic injury to an abnormally elevated coagulation time was a significant feature in jaundiced patients. In most instances, intravenous injection of such a hemostatic substance as calcium chloride, or of glucose, or transfusion of blood, suffices to lower a prolonged coagulation time to within normal limits, even though, in some cases, such reduction is sustained for a period of only a few hours. Should this be the case, one should govern the interval between the transfusion and the operation accordingly.

With the history of painless jaundice, and an abnormally prolonged coagulation time, one is more hesitant about carrying out an operative procedure than if, from the history, one would be led to believe that the obstruction was the result of stone. In such cases a period of delay, even though it necessitates allowing the patient to return home, will often suffice to clarify the diagnosis and present exact indications for exploration.

---

*From the Division of Surgery, The Mayo Clinic, Rochester, Minnesota. Read before the Inter-State Postgraduate Medical Association of North America, at Milwaukee, October 21, 1931.

Of jaundiced patients, renal function always should be determined, for not infrequently it is abnormally decreased. Preoperative study of the blood urea of a patient who was recently operated on revealed accumulation of 150 mg. in each 100 c.c. The value for urea decreased rapidly, with improvement in renal function, under eliminative procedures such as intravenous injections of hypertonic solutions of glucose, drastic catharsis, and hot packs, to the extent that successful cholecystectomy, with removal of stones, and choledochostomy were carried out, in spite of the fact that the patient was seventy-five years of age.

It is worth while dwelling on the influence of age as a factor in operative mortality. On other occasions, I have emphasized the fact that it is the patient's general condition and not his age which is one of the determining factors in operative mortality, substantiating this argument by presentation of several patients between the ages of sixty-nine and eighty years, on whom I have successfully performed extensive gastric resection for carcinoma. A similar ability of elderly patients to withstand operations on the gallbladder and common bile duct, even when accompanied by jaundice, is apparent. Certainly when male patients aged from seventy-five to eighty-five years, in satisfactory condition, are able to withstand prostatectomy, it would seem that there would be no reason why an intra-abdominal operation should be looked on with any greater hesitation.

The presence of purpuric spots on the skin of jaundiced patients has been regarded by some as a danger signal, which should not be passed without pause. Although I am not able at present to present the exact statistics, I am rather of the opinion that their presence as indications of greatly increased operative risk has been overemphasized. Their presence often has been noted in jaundiced patients whose coagulation time has been within normal limits, and whose postoperative course has been uneventful. I do not recall a single patient with such purpuric spots who has been denied operation, unless, for other reasons, operation was obviously unwise at the time it was considered.

THE SIGNIFICANT FEATURES IN THE OPERATIVE FINDINGS ADEQUATELY EXPLAINING THE TYPE OF BILIARY OBSTRUCTION

Satisfactory results in surgical treatment of jaundiced patients depend on adequate and complete relief of the obstruction. For purposes of this discussion, the obstructions can be limited to stones in the common and hepatic bile ducts, strictures, tumors of the pancreas and of the ampulla of Vater, and finally the obstruction seen in that group of cases of subacute cholecystitis in which the jaundice is apparently the result of associated cholangeitis and pancreatitis.

The appearance of the gallbladder and the common bile duct.—When the obstruction is inflammatory in origin, whether secondary to stones or stricture, the walls of the gallbladder are thickened and its color usually is changed from the normal bluish-green to a cream. When the obstruction of the common bile duct is pancreatic in type, the color of neither the gallbladder nor of the common bile duct is changed, unless there is an associated infection, with cholelithiasis, which occurs but rarely. With the wall of the gallbladder showing signs of inflammation, with stones absent as far as palpation reveals, and with jaundice present, the probabilities are that a stone is present in the common or the hepatic duct. Such stones denote their presence by thickening and change in color of the walls of the common bile duct and increase in its caliber. Many stones in the common duct can be palpated, but stones in the ampulla are frequently overlooked unless the duct is opened and carefully explored with probe and scoop. Even then, the scoop or probe may slip by a small stone nestling in the ampulla, and it is always advisable to palpate the duct with scoop or probe in it, which makes a small stone more prominent. Wherever the size of the duct permits, it is of value to use the little finger as a probe, inserting it in both directions of the duct, to make sure that a stone is not being overlooked. When stones have been removed from the common or hepatic duct, it is my custom to see to it that a probe or scoop of large size can be passed through the lower end of the ampulla into the duodenum, thus being certain that obstruction has been relieved, and at the same time accomplishing sufficient dilatation of the ampulla so that a stone, smaller in diameter than that of the scoop, can pass spontaneously into the duodenum.

When the gallbladder shows evidence of subacute inflammation and a mild degree of jaundice is present, when the common bile duct is normal in size and no stones are apparent to the one who is exploring with the scoop, the probabilities are that the associated cholangeitis and pancreatitis have been the causes of the mild degree of jaundice. Such explanation, however, should be accepted only after the most thorough and painstaking search of the tract for stones. Failure of jaundiced patients to recover when stones of the common and hepatic ducts have been present, is, in most instances, due to the fact that stones in the duct have been overlooked and have later dropped down, to produce an obstruction which is increased to the extent that hepatic and renal insufficiency occur.

Tumors of the head of the pancreas.—The head of the pancreas, as well as its body, should be palpated as a part of the examination of the biliary passages. With a mass in the head of the pancreas, and distention and normal color of the common bile duct and gallbladder, the obstruction is most surely one of the pancreatic portion of the common bile duct. In approximately 33 per cent of cases the lower end of the common bile duct passed posterior to the pancreas rather than through it, and in this minor group of cases, a tumor in the head of the pancreas does not produce jaundice until late. With a tumor in the head of the pancreas, the differential diagnosis of a malignant lesion and a benign one can be accurately made only by removal of a specimen for microscopic diagnosis. This usually is inadvisable because of the risk of such procedures, and because of the fact that a surgical procedure, in either instance, should be directed to relief of the obstruction and not to attack on the lesion itself. Study of the progress of patients following relief of obstructions due to tumors in the head of the pancreas indicates that approximately 15 per cent of the obstructions were the result of inflammatory changes. This should strike an optimistic note in a discussion of the lesion with the patient or his relatives. If the lesion is inflammatory, relief of the obstruction is followed by lasting good results. Even though the lesion is malignant, jaundice and itching are relieved by anastomosis of the biliary channels and the intestine, and the patient is able to enjoy months and frequently years of comfort. The malignant tumor in the head of the pancreas grows slowly, but in its later stages may produce sufficient deformity of the duodenum to interfere with the passage of gastric and duodenal content. In such cases, provided the patient's condition permits, gastrojejunostomy as a palliative procedure will still further prolong his life.

Condition of the duodenum.—The possibility of a large, perforating ulcer on the posterior wall of the duodenum, penetrating the pancreas and producing obstruction of the common bile duct by extension of the inflammation to surrounding structures should be remembered as a possible cause of biliary obstruction. Such a lesion is likely to be overlooked, due to its low position in the duodenum and the difficulty of its visualization in roentgenologic examination. This is particularly true if the patient has been operated on previously for disease of the gallbladder. A history of intermittent pain in the right upper quadrant of the abdomen, and the finding of a normal appearing common bile duct should immediately call attention to the possibility of such a duodenal lesion.

Tumors of the ampulla of Vater.—Such tumors, although they occur relatively infrequently, produce in general a painless type of jaundice, or, if the lesion becomes ulcerating, may be the source of severe intestinal hemorrhage. Since it is a relatively rare condition, it is more likely to be overlooked. In a recent case in which I successfully resected the ampulla and the posterior wall of the duodenum, with simultaneous anastomosis of the common bile duct to the duodenum, the carcinomatous lesion was small and of low degree of malignancy (adenocarcinoma graded 2). The small size of these lesions, their low degree of malignancy, their tendency to produce biliary obstruction with jaundice early and metastasis late, make early diagnosis and localization of the lesion important, and its surgical removal valuable.

MEASURES DIRECTED TOWARD RELIEF OF THE OBSTRUCTION

Following removal of stones from the common bile duct, the opening of the duct is sewed around a catheter, and this is left in place for approximately twelve days. The reason for this is that there is a probability that subsequent to the manipulation of the interior of the duct with a scoop sufficient edema or hemorrhage might produce temporary obstruction, and interfere with the patient's recovery. The catheter, therefore, serves as a safety valve. When there is associated hepatitis and pancreatitis, particularly in that group of cases in which the jaundice has not been accompanied by stone in the common or hepatic duct, prolonged drainage of the duct, for six to eight weeks or longer, is advisable. Such being the case, drainage is better accomplished by means of a small T-tube than by a catheter. A rubber tube or catheter should never be placed completely within the duct without its distal portion projecting through the papilla of Vater into the duodenum. With such projection through the papilla of Vater into the duodenum, intestinal peristalsis usually will pull the catheter completely into the lumen of the intestine, from whence it is spontaneously evacuated with the movement of the bowels. On the other hand, the ampulla or papilla of Vater would serve as a too effective barrier to passage of a piece of tube placed entirely within the duct. On one occasion, I removed such a tube, which a surgeon in another city had inserted into the duct two years previously; it was encrusted with bile salts.

Strictures.—When sufficient normal duct remains above the stricture to make possible accurate anastomosis of the remaining portion of an opening made in the duodenum, permanently good results can be expected, unless there is associated cholangeitis or hepatitis. In a group of patients whom I operated on for stricture of the common or hepatic bile duct, in thirteen of whom sufficient duct remained above the stricture into the duodenum to enable it to be anastomosed accurately to an opening in the duodenum, eight patients have had no further evidence of disease of the biliary tract, neither colic, jaundice, nor chills and fever. In several of these cases, more than four years have elapsed since operation. When the stricture is at the juncture of the common and hepatic ducts, and insufficient duct remains for accurate anastomosis to the duodenum, occasional good results are obtained by excision of the stricture, with direct anastomosis of the ends of the duct. It must be ascertained, of course, that the distal portion of the duct is patent. Although this type of operation for stricture has not been in particular favor, due probably to the fact that, associated with the stricture, sufficient infection remained in the duct so that partial contracture of the anastomosis probably occurred, with recurrence of symptoms of incomplete obstruction, mild, however, in degree. When the stricture is complete, and involves the common and hepatic ducts, establishment of an external biliary fistula, which later can be coned out and transplanted into the duodenum, has given very satisfactory results. Last year, I reported five such cases in which I had operated, in three of which excellent results had been obtained.

If a patient presents himself with an external biliary fistula, having been operated on elsewhere, before considering transplantation of the fistula the condition of the common and hepatic ducts and gallbladder must be ascertained. For example, if an egg-white material is excreted, the probabilities are that the gallbladder remains and that there is a stone in the cystic duct. When bile is excreted, the probabilities are that the obstruction is in the common bile duct, and that it is due either to stone, stricture, or tumor of the pancreas. If transplantation of an external biliary fistula is deemed the procedure of choice, it must adequately drain the intrahepatic ducts, and the latter must be free from stones; otherwise, the obstruction will recur. Furthermore, the possibility of a more certainly curative type of operative procedure, namely, hepaticoduodenostomy, should be considered if sufficient normal duct remains above the stricture or the fistula to enable the duct to be accurately anastomosed to the duodenum.

When a tumor in the head of the pancreas is the cause of the biliary obstruction, cholecystenterostomy relieves the jaundice and prolongs the patient's life, in a satisfactory manner, for from fourteen to forty-eight months. When the condition of the patient is such that the operation can be carried out as a primary procedure, in one stage, such is the preferable procedure. On the other hand, if patients are in unsatisfactory general condition, there is a field for the operation in two stages in which biliary drainage by cholecystostomy is first established, with improvement in the function of the liver and kidneys and in the patient's general condition. Ten or twelve days later, the second stage of the operation can be carried out, at which time the gallbladder can be anastomosed to the stomach or duodenum. These methods were used last year at the clinic in ten cases of cholecystenterostomy for tumors in the head of the pancreas with obstructive jaundice, with recovery in nine. An equal number of patients were operated on the previous year with similar results. It should not be forgotten that in a consideration of cholecystenterostomy as a procedure of value, in pancreatic obstruction of the common duct, the patient, in addition, has received the benefit of exploration of the biliary passages, eliminating the possibility of a so-called silent stone of the common duct.

INDICATIONS OF SATISFACTORY POSTOPERATIVE PROGRESS

The most certain indication of satisfactory progress subsequent to operation is the general appearance of the patient, his feeling of well-being, a normal output of bile and of urine of normal color, and temperature and pulse rate within normal limits. From 150 to 400 c.c. of bile of normal color excreted in each period of twenty-four hours, is satisfactory evidence that hepatic function is normal. Should blood appear in the bile, one must be alert to prevent it from clotting in the tube or in the duct, producing secondary obstruction. If, in association with bleeding from the wound, there is blood in the bile, the situation should be regarded as of considerable seriousness, and transfusion of blood given immediately and again as often as necessary. Should the bleeding continue, one should unhesitatingly open the incision, carry out exploration of the operative field to determine the site of the bleeding if possible, and control it. In a recent case, following removal of stones from the common bile duct and the gallbladder, secondary hemorrhage occurred, necessitating reopening of the incision on two occasions. On the former occasion, the operation was done in the patient's room and on the latter, in the operating room; the second time, it seemed likely that the patient might expire while the exploration was being carried out. The point of origin of the bleeding was identified, and the bleeding controlled; the blood clots which had accumulated above the liver, depressing and twisting it, interfering thereby with the circulation in the inferior vena cava, were evacuated and the patient recovered. Similar depression of the liver occurred four years ago in a case in which operation had been performed for stricture of the common bile duct; the depression occurred from leakage of bile. After the incision had been opened in the patient's room on the night of the operation, bile gushed from above the liver. This discharge was followed by a fairly rapid decrease in pulse rate from 160 to within normal limits. The respiratory rate decreased from 36 to normal, and the patient made a satisfactory recovery.

Studies of renal function, of the degree of jaundice, and of the coagulability of the blood should be carried out subsequent to operation. With the decrease in the amount of bile in the blood, there is no question that the obstruction has been adequately relieved. Should the coagulation time be increased, measures directed to its decrease should be considered. An intake of fluid of 2,500 to 3,000 c.c. daily should be insisted on. A portion of this fluid can be taken satisfactorily by proctoclysis in the first few days of convalescence, when the patient is unable to tolerate any considerable quantity of fluid by mouth. The use of physiologic solution of sodium chloride given subcutaneously or intravevenously twice daily in a quantity of 1,000 c.c. use of a 10 per cent solution of glucose in physiologic solution of sodium chloride, given intravenously twice daily in a quantity of 1,000 c.c. at each administration. If the amount of bile drained is scant, but the jaundice stationary, use of one of the cholagogues may stimulate the liver sufficiently to cause it to excrete a greater amount of fluid, and finally, should the condition of the patient be such that one is uncertain as to whether bleeding is occurring or the drainage tube is obstructed, or if the obstruction is inadequately relieved and the patient's chance of recovery seems seriously handicapped, exploration of the operative site should be undertaken with the least possible delay.

PRESIDENT'S LETTER

THE medical profession of today faces many important problems that a comparatively few years ago appeared on the horizon merely as faint clouds. There is evidence that our national and state organizations are alive to the need; first, of study of these problems in a fair-minded way and, second, based on that study of concerted action in giving advice as to how these problems may best be solved to the advantage of the public and of the profession. If the medical profession does not give heed to these problems, enthusiastic laymen will have enacted into laws their ideas of a solution which may in reality be positively harmful. The average busy practitioner cannot be expected to devote time to such problems, but it should be recognized that there are available certain of our members who are qualified by knowledge and adaptability to consider and discuss them. These members may or may not be leaders in scientific medicine, but they are nevertheless justly worthy of such recognition because of their knowledge of medical economics. It is unfortunate that men of this type, who are known to be public spirited and unselfish, are often spoken of scornfully as being medical politicians. In the next breath the same critic may enthusiastically insist on the organization and protection of the rights of the profession! Occasionally one hears complaints about the cost of maintaining our state organization. In my opinion the annual dues to our state association directly and indirectly give more in return to members than any like amount that is spent. Since our state organization has become more closely united and since we have had a salaried medical secretary, the Basic Science Act has been passed in our state, the Statute of Limitations has been reduced to two years, and the Medical Practice Act, which protects the people against quacks, cultists, and so forth has been established. The members of our legislative committee are not infallible; they are treading uncharted paths and the going is often hard. There is much yet to be done, and it is even more important to see that what has already been done is not nullified. Constant watchfulness over legislative activities is essential.

Industrial insurance cases comprise an increasing part of the work of the profession of our state. There has been, and still is, disagreement between the profession and insurance companies. This is not as serious as it appears. If insurance companies had the sole right irrespective of conditions to designate the medical attendant, and the patient or the insured person had no right or voice in the selection, the situation would be capable of abuse. If, on the other hand, the patient had the sole right to select his own medical attendant and the insurance company had no right or voice in the matter, the situation would be equally bad. There must be an intermediary position, satisfactory to all parties, so that the rights of the individual will be fairly protected and no unnecessary hardships endured.

The Minnesota State Medical Association has not only been alive to its own problems but it has been largely responsible for the present activity of the American Medical Association in showing that the plan of the Veterans' Administration, to increase the number of hospital beds, is vicious, and provides needless duplication of hospital space. There is a large number of beds available in civilian hospitals all over the country. On the committee appointed conjointly by the American Medical Association, the American Legion and the Veterans' Administration are Dr. Ben Wright, Dr. E. A. Meyerding, Mr. E. B. Cliff, Mr. Paul Fessler, and Mr. A. M. Calvin, all from Minnesota. The rapidity with which the Minnesota plan is being adopted throughout the country by other state associations is exemplified by the general raising of annual dues, and by the employment of full-time secretaries both in the state, and in larger, local medical organizations.

M. S. Henderson.

President,
Minnesota State Medical Association.

THE STATE MEETING

There is no indication of "repression" in the program of the coming State Medical Meeting which appears in this number of the Journal.

The two and a half days of presentation of scientific material have been divided for the most part between the medical and surgical sections with joint sessions for such subjects of widespread interest as transurethral prostatectomy, malignancy, and the numerous demonstrations listed. Movie fans will be able to observe the application of the cinema in medical instruction.

There is no subject more alive in our present economic crisis than that of the hospital care of veterans. The subject is one of fundamental economic importance to the hospitals, medical profession, and taxpayers. That the present method of furnishing hospital care for veterans and the proposed expansion of hospital facilities is an extravagant and unsatisfactory way to furnish this service is the contention of our profession. This subject will dominate the Economics meeting this year.

It has been said that there is nothing new under the sun. This year's program contradicts such a contention. Those who attend the meeting will find much mental stimulation.

ROCKY MOUNTAIN SPOTTED FEVER IN MINNESOTA

A case of Rocky Mountain spotted fever[1] reported recently from Minneapolis focuses the attention of Minnesota physicians on the possibility of this disease being endemic in the State.

In 1915 George Douglas Head[2] of Minneapolis reported a case of typhus fever which occurred in Minneapolis. Whether this case was one of Rocky Mountain spotted fever or typhus is impossible to say. Clinically these two diseases are almost impossible of differentiation. At that time laboratory methods were not sufficiently developed to make the distinction. Kemp and Grigsby[3] have reported a case of Rocky Mountain spotted fever in the vicinity of Dallas, Texas. Badger, Dyer and Rumreich[4, 5] have described cases of Rocky Mountain spotted fever occurring in Virginia and have noted variations in the animals inoculated with virus obtained from Montana as compared with animals inoculated with the virus obtained from the East. There was less virulence associated with Eastern virus. They have suggested calling the two types Eastern and Western, respectively. It is to be noted that the strain isolated in Minnesota differs in its reaction in guinea pigs from the Eastern and from the Western strain, but immunizes against either strain.

Badger, Dyer and Rumreich also were able to show that the dog tick (*Dermacentor variabilis*), distributed throughout the Eastern areas where Rocky Mountain spotted fever has been found, is able to transmit the disease. *Dermacentor andersoni* (also called *Dermacentor modestus*), the transmitter of the moutain strain, is strictly limited to the intermountain area between the Cascades and Rockies from the northern border of the United States as far south as Southern Nevada and Utah. Maver[6] had previously reported *Dermacentor variabilis* as a carrier and also showed *Dermacentor marginatus* and *Amblyom-*

ma Americanus as possible transmitters. *Dermacentor occidentalis* has been shown to transmit the disease on the West Coast (California).

Toomey[7] describes the Eastern area of distribution for the Eastern type of Rocky Mountain spotted fever from the southern border of New York to the northern border of Florida and from the Atlantic coast line to the Appalachian mountains. If this is correct, what of the cases reported in North and South Dakota and Nebraska and of our own case in Minnesota? Toomey limits the original Rocky Mountain spotted fever to the distribution of *Dermacentor andersoni.* The finding of this disease in states east of the Rockies extending to the Atlantic seaboard raises the question, has the disease always been endemic in regions east of the Rockies or has there been a migration of the disease from the epidemic area due to some ecological imbalance? Along this line one can assume that the reservoirs (rodents) certainly have been disturbed by cultivation, deforestation, railroads, automobiles, etc.

There are three ticks common in Minnesota: the dog tick (*Dermacentor variabilis*), the rabbit tick (*Hemaphysalis leporis palustris*), and the bird tick (*Hemaphysalis cinnabarina*). Of these the dog tick is the transmitter in this State because it is the only one which feeds on man.

Dr. Parker states that: "Nearly ten thousand ticks have been tested at the U. S. Public Health Service Laboratory at Hamilton, Montana, in coöperation with Dr. R. G. Green of the University of Minnesota Medical School, and in excess of one per cent of the American dog tick, *Dermacentor variabilis,* and two per cent of the rabbit tick, *Hemaphysalis leporis palustris,* have provoked reactions in laboratory animals which, had the ticks been collected in a known endemic area, would be considered definite evidence that the ticks concerned were carrying a low grade Rocky Mountain spotted fever virus."

During the coming months it would be well for physicians of this State to be on the watch for obscure fevers with rashes as possible cases of spotted fever. The blood of all suspects should be sent in to the State Board of Health for the Weil-Felix reaction. The Weil-Felix reaction is common to both typhus and Rocky Mountain spotted fever. Dr. H. A. Reimann, of the Department of Medicine of the University of Minnesota, will be glad to check all positive cases by cross immunological test on animals. In this manner the prevalence of spotted fever and its characteristics in Minnesota will be realized.

IMMUNITY AND HYPERSENSITIVITY

We must remain so alert to the general trend of opinion based upon investigation in such a bewildering variety of fields that all too often we, as general readers, give up. So-called practical minds decry what they term theoretical hair splitting to the point that far too much time elapses between the announcement of victorious research and its therapeutic application by physicians. It is likely that insulin has come into use all too slowly and years will elapse before the present hematopoietic stimulants are used with even the decisiveness presently known and proven.

A recent excellent review of staphylococcus infection in a report* of the "General Staff Conference of the University Hospitals" has much of interest in terms of this ubiquitous invader and those aware of its possibilities need not be told to approach boils and carbuncles with circumspection. However, I wish particularly to draw attention to the thought expressed in the report which is crystallizing about Clawson's teaching that there is a profound difference in the animal reaction to intramuscular and intravenous injections of killed bacteria (vaccine). The latter seems to decrease sensitivity, the former to promote it. Sensitivity and immunity or healing do not appear to proceed coördinately. A supersensitive host appears to predispose to exudative reactions, confronting the presence in the tissues of the autogenic source. With staphylococci it is a series of abscesses among which kidney and bone foci stand out conspicuously. In tuberculosis localized nidi (such as, for example, caseating glands), with tissue supersensitivity lay the foundation for allergic subclavicular extensive exudative Assmann-Redeker reactions. In subacute bacterial endocarditis the blood stream is actually fed live virulent organisms. The titer for their agglutination may rise enormously high. Wherever these embolic masses lodge there is little exudation and never abscesses.

The work of Petroff, Florence Sabin, and others, experimentally, injecting the fraction products of tubercle bacilli into animals, appears to prove that the sensitivity and allergy are promoted by the protein fraction, and immunity by the lipoid portion. Such studies may ultimately straighten out the devious tangle of BCG and establish less mooted tuberculosis prevention. In the meantime less gifted and endowed humble practitioners may well hesitate in the use of general and specific vaccines, at least in boils and "rheumatism," and leave to further investigation the answer to the possible use of intravenous vaccines where desensitization appears of therapeutic benefit.

THE MEDICAL CARE OF VETERANS

The apparent present status in Minnesota

We hope you all have read the page on medical care of veterans in the April number of Minnesota Medicine. The committee of the Ramsey County Society has continued its good work; we understand that several Ramsey County Legion Posts have taken an interest in the problem. In Hennepin County a committee has been at work since January. The doctors are well informed and several Posts have expressed their interest. The District Dental Society is becoming actively interested also. We hear that the problem is receiving careful attention on the part of medical societies and Legion Posts throughout the state.

Resolutions in support of several different plans for the care of veterans have been passed, some of them on insufficient information, and, insofar as I can see, with very little prospect of support from the Legion of the State or from the medical profession as a whole.

At the recent spring conference of the Minnesota Department of the Legion there were many frank informal discussions between interested physicians in and out of the Legion and the leaders of the Minnesota Legion's rehabilitation work. Coöperation between the Legion and the medical profession is essential in solving the problem. In this state it should be relatively easy to establish a basis for coöperation.

While I cannot at this time speak for the Committee on State Health Relations, it seems to me that it may be helpful to give some statement of the problem as I see it in order to reduce the points of argument to a minimum. Fortunately in Minnesota the Legion has studied the problem intelligently and has been leading the national Legion in that matter.

We seem to be agreed on the present accepted practice that disabilities of service origin as well as tuberculosis and nervous and mental diseases, because of presumptive service connection, should be cared for in veterans' hospitals. It must be remembered in this connection also that the Veterans Bureau provides that, in case of emergency, service-connected disabilities may be hospitalized in their home communities at government expense.

The Minnesota department of the Legion last year proposed that the right to be hospitalized in his home community at government expense be extended to the veteran suffering from a non-service-connected ailment in case of emergency. It seems to me that we should have no hesitation in doing all we can for the adoption of such a plan.

The care of medical and surgical non-service-connected disabilities not constituting emergencies is still under discussion, and many of the questions raised are far from solution; doctors themselves do not seem to agree in some respects.

The Minnesota Legion leaders say that in their experience in this State they have made satisfactory progress only when they have attacked the veterans' problems one step at a time. They insist that their proposal for emergency care of veterans in their home communities must be proven effective in practice before they will endorse any extension of the principle to non-emergency cases.

It seems to me that there is much to say in favor of that idea. Emergency cases are the ones most in need of prompt care close to home. Adoption of such a plan will destroy the strongest arguments used in favor of the construction of additional veterans' hospitals. If it can be proved that veterans can receive as good care or better in their home community hospitals by doctors of their own choice in cases of emergency, it will be easier for the Legion and others to believe that such care would be good in other cases.

The above ideas are not given officially, but rather to stimulate thought and discussion. If you have other ideas please let the Committee on State Health Relations hear from you at once. We hope that the State Medical Association and the Minnesota Department of the American Legion through continued coöperation can work together toward some satisfactory solution of the entire problem of the medical care of veterans.

T. H. Sweetser.

COÖPERATIVE CLINIC TOURS

Perhaps sufficient emphasis has not been given in our columns to the foreign clinic tours which have been arranged by the various State Medical Journals with the Amerop Travel Service for this summer. Notice has just been received that reductions in rates by the steamship companies have resulted in a lowering of the figures for the clinic tours stated in our last issue of the Journal. First class accommodations have been reduced

$150 and tourist $47.50, which makes the clinic tours this summer more attractive than ever. It will be noted that all three tours provide for attendance at the Centennial Anniversary meeting of the British Medical Association, a further special attraction this year. Clinics are being arranged in the principal cities of Europe, London, Paris, Vienna, and Berlin. Choice of the steamers Bremen and Europa of the North German Lloyd Line leaves nothing further to be desired in the way of accommodations.

The State Journals have no hesitation in recommending these Clinic Tours to Association members and believe the trips will offer valuable clinical opportunities combined with a vacation trip abroad. Further details may be obtained upon inquiry at the office of MINNESOTA MEDICINE or by writing direct to Amerop Travel Service, 132 North LaSalle Street, Chicago.

OF GENERAL INTEREST

Dr. Rollin E. Cutts, formerly of the Mayo Clinic, Rochester, Minnesota, is now associated with the Vicksburg Clinic, Vicksburg, Tennessee.

Dr. H. J. Fortin, formerly of the Mayo Clinic, Rochester, Minnesota, has opened offices at 802 Black Building, Fargo, North Dakota.

Dr. H. C. Thornton is now on the staff of the Indianapolis City Hospital, Indianapolis, Indiana. He was formerly associated with the Mayo Clinic, Rochester, Minnesota.

Dr. V. S. Cabot has been elected chief of staff at St. Barnabas Hospital, Minneapolis, with Dr. Joseph Hedding, vice president, and Dr. W. B. Holt, secretary-treasurer.

Dr. J. F. McClendon, professor of Physiological Chemistry at the University of Minnesota, has arrived in Japan, where he will conduct research work in iodine and goiter as a visiting professor at Tohoku Imperial University.

The new infirmary building of the Walker Sanatorium, which was formally opened early in April, will accommodate eighty patients and has facilities for emergency operating rooms, staff consultation room and library, and clinical examination rooms.

Dr. F. C. Rodda, Minneapolis, was guest speaker at the last regular meeting of the Washington County Medical Society held March 8 at the Stillwater Club rooms. Dr. Rodda's subject was "Deficiency Diseases of Childhood."

Dr. Leonard G. Flannagan has become associated in practice with Drs. Leck and Morrow at Austin, Minnesota. Dr. Flannagan is a graduate of the University of Minnesota and has been affiliated with the Lakeside Hospital, Cleveland, Ohio. His specialty is the treatment of diseases of the eye, ear, nose and throat.

INTENSIVE EUROPEAN SUMMER COURSE

The eleventh intensive European summer course in Ophthalmology and Otolaryngology and the second in Surgery, Gynecology and Obstetrics under the direction of Dr. George W. Mackenzie, of Philadelphia, will be held in Vienna from July 8 to August 19 inclusive. The M. S. St. Louis sails June 25, which will allow for a few days in Berlin. Some fifty hours of lectures on ship-board are included in the course. For details address Dr. George W. Mackenzie, 1724 Spruce St., Philadelphia.

STATE BOARD OF MEDICAL EXAMINERS

NEGRO QUACK VIOLATES COURT ORDER AND LANDS IN COUNTY JAIL

State of Minnesota *vs.* Robert McGraw

Robert McGraw, negro quack of itinerant fame, has discovered, much to his sorrow, that he could not violate the terms of a suspended sentence given him last June by Judge Tifft, Glencoe, Minnesota, and get away with it. On June 12, 1931, McGraw entered pleas of guilty to two charges of practicing healing without a Basic Science Certificate before the Honorable C. M. Tifft, Judge of the District Court, and was fined $225.00 and costs on the first charge and given a suspended sentence of one year in the County Jail on the second charge. McGraw at that time expressed an ardent desire to return to his native State of Illinois. One of the conditions of the suspension of sentence required McGraw to refrain from the practice of healing in the State of Minnesota until properly licensed.

The State Board of Medical Examiners discovered that in the fall of 1931 McGraw came into Lyon County, Minnesota, and extracted the sum of $250.00 in cash to cure an alleged case of cancer. At that time McGraw was located in Sioux City, Iowa. About the first of March, 1932, McGraw moved back into Todd County, Minnesota, and located on a farm some four miles northeast of Bertha. Following an investigation of the Medical Board, Judge Tifft, on April 2, 1932, revoked the suspension of sentence and ordered McGraw committed to the McLeod County Jail to serve his one year sentence. On April 5, McGraw was arrested on the Henry Paschke farm in Todd County and returned to the McLeod County Jail, where he is now confined according to law. This is the first time since the enactment of the Basic Science Law in Minnesota that a quack has been ordered to serve the maximum sentence provided for a violation of the law.

SQUIBB ADEX TABLETS 10 D NOT ACCEPTABLE FOR N. N. R.

The Council on Pharmacy and Chemistry reports that it refused recognition to the name Adex Tablets 10 D for a cod liver oil concentrate fortified by addition of viosterol. The Council has repeatedly called attention to the fundamental importance of the rules designed to prevent the multiplication of names for the same product. This rule provides that the discoverer of a new product or of a new and sufficiently important therapeutic use for an old product may give it an arbitrary name. Squibb & Sons are not the first to prepare a cod liver oil concentrate nor does the addition of viosterol to a cod liver oil concentrate present a discovery. While Squibb & Sons deserve credit for the efforts which they have made toward increasing the potency and stability of cod liver oil concentrates, other firms have worked in the same direction. The Council decided that it could not recognize the name Squibb Adex Tablets 10 D because the application of a proprietary name to this product is not in the interest of the medical profession or the public and declared Squibb Adex Tablets 10 D unacceptable for New and Non-official Remedies. (Jour. A. M. A., March 19, 1932, p. 983:)

A FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

A patience and determination of almost Jovian proportions are needed by a medical profession that proposes to educate the public in modern methods of disease prevention. Such is the opinion of Dr. J. R. Neal of Springfield, Ill., president-elect of the Illinois State Medical Society, expressed recently before the Chicago Medical Round Toble.

To those medical economists who have been in the habit of dismissing public health education as a simple matter and less important, perhaps, than purely legislative activity, the following excerpts from Dr. Neal's paper may be of especial interest.

Dr. Neal regards the state of public knowledge of modern disease prevention as comparable to the state of mind of Indian savages when the savages were first introduced by the French to civilized government and a civilized religion. The Indians watched and listened, deeply impressed. But when the ceremonies were over and the voyageurs had departed they reverted to the Great Spirit and, incidentally, stole the metal arms of France from the cross for bullets for their new guns. Ultimately many of the Indians did adopt the white man's ways and some rose to high levels of civilization. These were the ones whose education began when they were children. But the progress was slow and it became noticeable only when it was possible to control the entire education of the children.

"Substitute the modern medical profession for the handful of French adventurers," says Dr. Neal; "let the public take the place of the Indians; and call scientific medicine the white man's laws and customs and we have, in 1931, an almost perfect reproduction of the scene enacted on the 14th of June, 1671, at Sault Ste. Marie.

"Scientific medicine, as we understand it today, is a very youthful development. Bacterial life and its relation to disease was discovered less than 100 years ago. Anesthesia has not yet celebrated its hundredth anniversary. The practice of faith healing, on the other hand, and of strange manipulations of the body, of invoking charms and of mixing the extracts of roots and herbs is as old as history itself. The idea that sickness originates from mysterious sources and that occult power, aided and abetted by incantations, is required to deal with it, harks back to the very earliest times.

"Entrenched as they are in the very marrow of the race these ancient traditions and superstitions will not be easily displaced. It is a difficult task even for the school to do the job, because the influence of parents frequently overbalances that of the teacher in such matters. . . .

"Some of the state medical societies have recently organized popular educational movements which are doing splendid, if limited, work. In Illinois, through speakers' bureaus and newspaper service and radio broadcasts, a very commendable educational work has been accomplished. Here, again, the magnitude of these efforts is diminutive in comparison with campaigns of education undertaken by the venders of nostrums and health foods. . . .

"Probably the most important and at the same time the educational results is the state normal colleges. Here the teachers who get hold of the children in the primary grades are trained. . . .

"The medical profession has recognized the importance of education. It has sometimes erred, however, in the method of enlightening the public. Most of its efforts have been expended along legislative lines. That way brings the quickest but, in many cases, the least return. It operates well among people who can choose wisely between the bona fide and the false and it is necessary as far as it goes. But more than one-half of our population has never been to high chool. For these, the influence of racial practice and belief is important. Traditions and customs as old as history are replaced in the public mind with the greatest difficulty. To do it one must begin with the child. Louis XIV could not sit upon his throne in Paris and transform by edict the customs and habits of a savage people 3,000 miles away."

OBITUARY

Dr. Eugene Hubbell

1855-1932

Dr. Eugene Hubbell, Saint Paul, died on April 20, 1932, following a short illness.

Dr. Hubbell was graduated from Hahnemann Medical College of Chicago in 1883, after which he practiced in Clearwater, Minn., for four years and later in Waseca for two years. He had been active in practice ever since he came to St. Paul forty-two years ago.

Dr. Hubbell was a member of the American Institute of Homeopathy, had served as president of the Minnesota Institute of Homeopathy and the Twin City Homeopathic Society. He had also been president of the American Association of Orificial Surgeons and the National Society of Physical Therapeutics. Dr. Hubbell was a member of the Allied Medical Association of America and the National Society of Medico-Physical Research.

Besides his widow, Dr. Hubbell is survived by three daughters, Mrs. R. A. Thuma of Saint Paul, Mrs. J. F. Gage of Atlanta, Ga., and Mrs. W. C. Scott of Chicago, and a son, Arthur C. Hubbell of Saint Paul.

Dr. W. J. Kremer

1878-1932

Dr. Walter J. Kremer, a member of the staff of St. Mary's hospital and consulting urologist of the United States Veterans' bureau, died Saturday, April 2, 1932, at the Veterans' hospital. He was fifty-three years old.

Dr. Kremer was born in Owatonna, Minn., April 25, 1878, and later moved to Cold Springs, Minn. After completion of a two years' academic course at St. John's University, he entered the University of Minnesota medical school, where he obtained his doctor's degree in 1911. After an eighteen-months' internship at the Minneapolis General hospital, Dr. Kremer began practice in Minneapolis.

During the World war he enlisted in the medical corps and was assigned to a base hospital at Camp Gordon, Ga., where he was commissioned a first lieutenant. After the war he resumed practice in Minneapolis.

He was a member of the American College of Surgeons, Minnesota State Medical Association, Hennepin County Medical Society, Minneapolis Clinical Club, the Urological Society of the Twin Cities and Nu Sigma Nu, medical fraternity. He was associate urologist at General Hospital, a former instructor in urology at the University of Minnesota, and formerly attending urologist at Park View Hospital.

Surviving are his mother and father, Mr. and Mrs. Ignatius Kremer of Cold Springs; two brothers, George of Fargo, N. D., and Charles of Cold Springs, and a sister, Clara, of Cold Springs.

Dr. John Vincent O'Connor

1867-1932

Dr. John Vincent O'Connor, Saint Paul, died at St. Joseph's Hospital on April 5, 1932, following a five weeks' illness.

Born in Minneapolis, September 1, 1867, of Irish parentage, he received his early education in the public schools in this state and in Ohio. After taking advanced musical instruction from Herman E. Zolk of Minneapolis, Dr. O'Connor became an accomplished pianist of unusual taste and ability. As a teacher of music he was enabled to pay his way through the medical course at the University of Minnesota, where he obtained his degree in 1895.

Dr. O'Connor practiced at Watkins, Minnesota, and later at Waverly, Minnesota, where he married Nellie Giblin, a native of Pennsylvania. After taking work at the New York Post-Graduate School and Hospital, he moved to Saint Paul in 1901, where he engaged in general practice until his final illness. He was one of the first tenants of the Lowry Building and joined the Ramsey County Medical Society, May 26, 1902.

Dr. O'Connor held the office of state examiner for the A. O. H. and was examiner for the Union Central Life Insurance Company. He was a member of the A. O. U. W., the M. W. A. and a charter member of the K. of C.

Dr. O'Connor is survived by his wife and five children, Gertrude H., Edna M., John G., Donald E., and Emmett J. O'Connor.

Dr. Lincoln E. Penny

1860-1932

Dr. Lincoln E. Penny, Saint Paul, died Monday, March 28, 1932, at the age of seventy-two, at St. Luke's Hospital after an illness of two days.

Dr. Penny was born in Arcadia, Wisconsin, in 1860. He graduated from Hahnemann Medical College in 1882 and Rush Medical College, Chicago, in 1885. After his graduation he moved to Saint Paul, where he practiced continuously until his death, a period of over forty years.

Dr. Penny served as a member of the staff of attending physicians at Ancker Hospital for thirty years.

Dr. Penny was a member of the American Institute of Homeopathy, and joined the Ramsey County Medical Society, the Minnesota State Medical Association and the American Medical Association in 1926.

In the passing of this beloved pioneer, an unexcelled example has been set to the younger generation by his honesty, professional courtesy and devotion to duty. Dr. Penny is survived by his widow, Mrs. Elsie Penny.

Dr. William Jesse Taylor

1844-1932

Dr. W. J. Taylor, pioneer physician in Minnesota, died at his home in Pipestone, Friday, April 15, 1932, at the age of eighty-eight.

William Jesse Taylor was born in Cataragus county, New York State, April 18, 1844. At the age of eight years accompanied his parents to Dane County, Wisconsin, and grew to manhood on a farm eight miles west of the city of Madison. He received his early education in the common schols of Dane County, later attending the University of Wisconsin and Rush Medical College.

He enlisted August 20, 1862, in Co. K., 32nd Wisconsin Volunteer Infantry, and served for nearly three years, being mustered out June 12, 1865. Following the war he returned to Wisconsin and completed his education.

He began practice of the medical profession at Black Earth, Wis., in 1873, but remained there only until May of the following year. In June, 1874, he made his first visit to Pipestone County, and at that time decided to make his future home there. While on this initial visit to the county, he participated in the first Republican county convention, attended by the only three men then in the county. Dr. Taylor was chosen to represent the county at the congressional convention at Owatonna later that year.

Dr. Taylor remained in the vicinity long enough to select his claim, as a soldier's homestead, and tree claim. He returned to Wisconsin and spent the winter of 1874-75 teaching in Dane County. In the spring of 1875 he again came to Pipestone County and built a house on his claim, remaining there until June. He returned to Wisconsin and remained there until March, 1876, when he came to Pipestone County to reside permanently, his wife joining him there later that year.

The crop on his farm being destroyed that summer by grasshoppers, Dr. Taylor went to Luverne to practice has profession, and spent most of his time there the next three years, his family meanwhile residing on his claim. In March, 1879, he returned from Luverne and arranged to practice in Pipestone. From that time he was for nearly fifty years active as a medical practitioner in this city and vicinity. At his office in Pipestone on June 7, 1888, the Southwestern Minnesota Medical Society was organized, and in 1901 Dr. Taylor was elected president of that society. He was at one time president of the Minnesota Public Health Association, and was a member of its board of directors at the time of his death, being re-elected last year. For some time he held the office of Surgeon in the Minnesota Department, G. A. R. He was for years a member of the Pension Examining Board for his district, and served as a member of the city and county health boards.

At different times Dr. Taylor had partners in the medical practice here, among these being Dr. Wm. McGillivray, Dr. George D. Rice and Dr. G. F. Schmidt. At a later time the Pipestone Clinic was organized with Dr. Taylor as a member, and during the last years of his practice he was associated, though not as a partner, with Dr. E. G. McKeown.

Dr. Taylor was active in civic and fraternal affairs and held numerous offices in these fields of endeavor.

Surviving are four children: Orville S. Taylor, St. Cloud, Minn.; Mrs. Luella McGillivray, Pipestone; Mrs. Oliver Bullard (Mayme), Spooner, Wis.; Mrs. Grant S. Beardsley (Maude), Eugene, Ore.; and Miss Jane Taylor, Everett, Wash.; also eight grandchildren, and one great grandchild. One brother, Orville J. Taylor, of San Diego, Calif., also survives.

Dr. Stephen O. Watkins

1851-1932

Dr. Stephen O. Watkins, eighty-one years old, died Monday, April 11, 1932, at the Masonic home in Bloomington, where he had lived for two and a half years.

Born at Amherst, N. H., Dr. Watkins practiced medicine in Minnesota for fifty years before his retirement in 1920. For several years he was physician for the Northern Pacific Railroad and lived at Carlton when it was called N. P. Junction. He was a charter member of Palestine Masonic lodge of Duluth.

Survivors are a daughter, Mrs. W. C. Carlson of Seattle; a son, S. Elmer Watkins of Phoenix, Ariz., and two sisters, Mrs. J. E. Green of Carlton, and Abby Watkins of Los Angeles.

A disease of the Rocky Mountain spotted fever type has been identified as occurring in States in the eastern and southeastern sections of the United States. During the course of field investigations of endemic typhus it became apparent that many of the cases observed differed materially in clinical aspects from endemic typhus as described by earlier investigators. It was noted that many of the patients suffered from a very severe disease which did not correspond to the clinical picture of endemic typhus and which resembled the spotted fever of the Rocky Mountains more closely than it did any other disease. Moreover, quite a high proportion of these cases gave a history of tick bite within a short time preceding onset. Laboratory studies confirmed the epidemiological findings. This eastern type of spotted fever has so far been found to exist in rural communities in Delaware, Pennsylvania, Maryland, the District of Columbia, Virginia, and North Carolina.—*Health News,* U. S. P. H. Service, March 29, 1932.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

PROGRAM 79TH ANNUAL MEETING MINNESOTA STATE MEDICAL ASSOCIATION, ST. PAUL AUDITORIUM

The Council will hold its first meeting at 6:30 p. m. Sunday, May 22, at the Lowry Hotel. It will meet again at noon, Monday, May 23, and at 2:30 Tuesday, May 24.

The House of Delegates will meet at 9 a. m. Monday, May 23, at the Auditorium, and for luncheon at noon Tuesday, May 24, at the Minnesota Club.

REFERENCE COMMITTEE

A. N. Collins	Duluth
C. B. Wright	Minneapolis
W. C. Carroll	St. Paul
O. E. Locken	Crookston
R. V. Williams	Rushford

SCIENTIFIC PROGRAM

Monday, May 23, 1932

SCIENTIFIC CINEMA

Exhibit Hall—1:00 to 4:30 P. M.

Selected scientific films will be shown all afternoon.

CLINICO-PATHOLOGICAL CONFERENCES

Surgical Hall—1 P. M.

Presiding Officer, Wm. A. O'Brien

Ancker Hospital Staff—J. F. Noble, Conductor, St. Paul

Mayo Clinic Staff—H. E. Robertson, Conductor, Rochester

St. Mary's Hospital Staff—E. L. Tuohy and G. L. Berdez, Conductors, Duluth

University Hospitals Staff—Wm. A. O'Brien, Conductor, Minneapolis

CLINICO-RADIOLOGICAL CONFERENCES

Surgical Hall

Mayo Clinic Staff—B. R. Kirklin, Conductor, Rochester

University Hospitals Staff—Leo Rigler, Conductor, Minneapolis

THE MINNESOTA RADIOLOGIC SOCIETY

Medical Hall

Radiological program at 2:00 P. M.

Monday Evening—May 23

Technical Exhibits (Open until 8:00 P. M.)

MEDICAL ECONOMICS MEETING

Auditorium Theatre—8 P. M.

Hospital and Medical Care of Veterans

Paul Fesler, President, American Hospital Association, *Chairman*

The Community Hospital—Edward A. Fitzpatrick, Dean, Marquette University, Milwaukee

The American Legion—E. V. Cliff, Ortonville

The Public—F. R. Bigelow, Saint Paul

The Doctor—Dr. Olin West, Chicago

Tuesday Morning, May 24

SECTION OF MEDICINE

8 A. M.

Presiding Officers—C. A. McKinlay, Minneapolis
A. M. Snell, Rochester

The Diagnosis and Treatment of Cardiac Arrhythmias—O. E. Locken, Crookston

Practical Aspects of Allergic Disease—F. W. Gaarde, Rochester

Symposium on Functional Disorders

Functional Gastro-Intestinal Disturbances — C. B. Wright, Minneapolis

Cardiac Neuroses—H. E. Richardson, St. Paul

Treatment of Affective Disorders—J. C. Michael, Minneapolis

The Element of Fear in the Development of Functional Disorders—A. D. Hoidale, Tracy

The Appeal of Quackery to the Neurotic Patient—W. C. Alvarez, Rochester

General Discussion—Opened by: E. L. Tuohy, Duluth

SECTION OF SURGERY

8 A. M.

Presiding Officers—George Earl, St. Paul
J. R. Manley, Duluth

Estimation of Disability in Industrial Cases—Edw. T. Evans, Minneapolis

Factors of Safety in Emergency Abdominal Surgery—V. S. Counseller, Rochester

Emergency Treatment of Eye Injuries—Hendrie W. Grant, St. Paul

Glandular Dysfunction as Related to the Sexual Hormone—George E. Hudson, Minneapolis

Intestinal Intussusception in Infants—J. M. Hayes, Minneapolis

Renal Factors in the Surgical Abdomen—Herman H. Jensen, Atwater

Hard of Hearing Problem—M. W. Wheeler, St. Paul

Fracture Work in the Smaller Community—B. J. Branton, Willmar

SCIENTIFIC CINEMA

8:20 A. M.

F. C. Schuldt, Chairman
F. H. Strom, Technical Adviser
D. A. Leonard, Projection Supervisor

Cancer Research—Lecturer: Wm. A. O'Brien, Minneapolis. Courtesy of the American Journal of Cancer

Repair of Second and Third Degree Lacerations of the Perineum and Rectocele—(Talkie.) Courtesy of Petrolagar Company

Delivery of Twins—Lecturer and Producer: J. J. Swendson, St. Paul

Cesarean Section—Lecturer and Producer: J. J. Swendson, St. Paul

Some Features of Hospital Administration—(Talkie.) Courtesy of Petrolagar Company

Anatomy of the Female Pelvis and Perineum—(Talkie.) Courtesy of Petrolagar Company

DEMONSTRATIONS

10 A. M.

The Physiologic Action of Animal Venoms—Hiram Essex, Rochester

Tuberculin Test—J. A. Myers, Lymanhurst School, Minneapolis

Blood Transfusion—H. E. Hullsiek, St. Paul

The Use of the Artificial Larynx—G. B. New and Charles Sheard, Rochester

Fresh Pathology—E. T. Bell, Minneapolis

Detection of Deafness (Group and Individual Tests)—M. W. Wheeler, St. Paul

Clinical Pathology—Including Congo Red Test for Amyloid, Friedman Hormone Pregnancy Test and Photoelectric Hemoglobinometer—A. H. Sanford and T. B. Magath, Rochester

Use of Ketogenic Diet in Urinary Infection. A Demonstration of the Effects of Diet on Bactericidal Power of Urine with Results in Treatment.
In children—H. F. Helmholz, Rochester
In adults—A. L. Clark, Rochester

Pathogenic Parasites in Man—Reed O. Christenson, Minneapolis

Phases of Bronchoscopy and Esophagoscopy of Importance in General Practice—Virgil J. Schwartz, Minneapolis

Diphtheria Immunization and Schick Test—B. F. Simon, St. Paul

Syphilis—Practical Points in the Therapy of—Paul A. O'Leary and L. A. Brunsting, Rochester

Trichomonas Vaginalis—Russell Moe, Duluth

Oleothorax—F. F. Callahan, Pokegama

Undulant Fever—Lucy Heathman, Minneapolis

Cholecystographic Technic—B. R. Kirklin, Rochester

Surgical Use of Maggots—Gordon MacRae, Duluth

Professional Pharmacy as Applied to the Physicians. Under the auspices of the Inter-Professional Relationships Committee of Hennepin County

GENERAL ASSEMBLY

11 A. M.

Fractures in and about the Neck of the Femur—W. C. Campbell, Memphis, Tenn.

Discussion—Emil Geist, Minneapolis; M. S. Henderson, Rochester

GENERAL ASSEMBLY

1 P. M.

Changing Attitudes towards the Malignancy Problem—Wm. A. O'Brien, Minneapolis

Discussion—W. J. Mayo, Rochester

SCIENTIFIC CINEMA

1 P. M.

Hemorrhoidectomy—An Anatomical Method—Lecturers and Producers: W. A. Fansler and J. K. Anderson, Minneapolis

Cancer of the Skin—Lecturer: Wm. A. O'Brien, Minneapolis. Courtesy of the American Journal of Cancer

Repair of Urethrocele, Cystocele, and Lacerations of the Cervix—(Talkie.) Courtesy of Petrolagar Company

Bone Tumors—Lecturer: Wm. A. O'Brien, Minneapolis. Courtesy of the American Journal of Cancer.

A Simplified Method of Filming Surgical Procedure Available to Everyone—Lecturer and Producer: L. A. Julin, *Rochester*

Surgical Technic of Nephrectomy, Pelviolithotomy, Ureterolithotomy and the Surgical Removal of Urethral Strictures—Lecturer and Producer: Waltman Walters, Rochester

The Tucking Operation for Strabismus—Lecturers and Producers—F. E. Burch and Hendrie Grant, St. Paul

Preliminary Hemostasis in Goiter Surgery—Lecturer Producer: Martin Nordland, Minneapolis

The Gillette State Hospital for Crippled Children—Lecturer: C. C. Chatterton, St. Paul

SECTION OF MEDICINE

2:30 P. M.

Treatment of Trichophytosis—L. A. Brunsting, Rochester

Recent Developments in the Treatment of Syphilis—H. E. Michelson, Minneapolis

The Use of Spinal Anesthesia in Gastric Crisis in Tabes—Gordon R. Kamman, St. Paul

Agranulocytosis—E. T. F. Richards and Kano Ikeda, St. Paul

Correlation between Clinical and X-ray Findings in Tuberculous Individuals—H. A. Burns, Ah-Gwah-Ching

Symposium on Pediatrics

Treatment of Epilepsy in Childhood—Irvine McQuarrie, Minneapolis

Present Status of Prevention and Treatment of Scarlet Fever—E. S. Platou, Minneapolis

Diagnosis and Treatment of Pyelitis—H. F. Helmholz, Rochester

Simplified Infant Feeding—O. W. Rowe, Duluth

Discussion—Opened by: W. R. Shannon, St. Paul; Thomas Myers, St. Paul
Globus Hystericus—Andrew Sinamark, Hibbing
Diagnosis of Laryngeal Disease—L. R. Boies, Minneapolis
Ocular Lesions of General Diseases—J. F. Brusegard, Red Wing
End-results Following Operations in Congenital Pyloric Stenosis—A. E. Sohmer and R. N. Andrews, Mankato
Some Clinical Aspects of Spinal Injuries—E. Mendelssohn Jones, St. Paul
Hyperparathyroidism—John de J. Pemberton, Rochester
Cervical and Abnormal First Thoracic Ribs—W. C. Carroll, St. Paul
Extra-uterine Pregnancy—Ivar Sivertsen, Minneapolis
Abscess of the Liver—A. N. Collins, Duluth
Surgical Treatment of Urogenital Tuberculosis—Gilbert J. Thomas, Minneapolis; Thos. J. Kinsella, Oak Terrace
Comparison of Duodenal Ulcer in Germany and the United States with Surgical Indications—Waltman Walters, Rochester; Walter Sebening, Frankfort-on-the-Main, Germany

ANNUAL BANQUET

Banquet Hall, Lowry Hotel
7 P. M.

Toastmaster—W. J. Mayo, Rochester
Address of Welcome—E. V. Goltz, President, Ramsey County Medical Society, St. Paul
The State Association—M. S. Henderson, President, Rochester, and the new President-elect.
The Women's Auxiliary—Mrs. Edward Schons, President-elect, Saint Paul
Your Medical School—Dean R. E. Scammon, University of Minnesota
Address—Reverend W. C. Sainsbury, Fargo, N. D.

Dancing

Open House—Ramsey County Medical Society Rooms, 15th Floor, Lowry Medical Arts Building

Wednesday Morning, May 25

SECTION OF MEDICINE

8 A. M.

Diverticula in the Gastro-Intestinal Tract—R. G. Allison, Minneapolis
Primary Carcinoma of the Lung—E. J. Simons, Swanville
Case Report on Epidemic Encephalitis—B. J. Cronwell, Austin
Sciatic Syndrome—W. P. Gardner, St. Paul
Recent Advances in Endocrinology—L. G. Rowntree, Rochester
Chronic Arthritis; Recent Studies on Etiology and Intravenous Vaccine Treatment:

1. Experimental Basis—B. J. Clawson, Minneapolis
2. Clinical Phases—Macnider Wetherby, Minneapolis
3. Discussion—Opened by: F. H. K. Schaaf, Minneapolis

SECTION OF SURGERY

8 A. M.

Important Points in Surgery of the Diseased Thyroid—Martin Nordland, Minneapolis
Anal Fistulæ—L. A. Buie, Rochester
Gradual Decompression of the Biliary System—John Culligan, St. Paul
Acute Intestinal Obstructions—W. G. Strobel, Duluth
The Noisy Ethmoids and Their Associates—W. L. Burnap, Fergus Falls
Sodium Amytal Anesthesia in Obstetrics—J. J. Swendson, St. Paul
Subdiaphragmatic and Liver Abscess—Walter G. Benjamin, Pipestone
Present-day Surgical Treatment of Carcinoma of the Rectum and Rectosigmoid—Fred W. Rankin, Rochester

SCIENTIFIC CINEMA—8:20 A. M.

Same Program as Tuesday Morning

DEMONSTRATIONS

10 A. M.

Retinal Vascular Changes—H. P. Wagener, Rochester
Spotted Fever and Tularemia—R. R. Parker, Hamilton, Montana, and R. G. Green, Minneapolis
Varicose Leg Ulcers—G. D. Brand, St. Paul
Chronic Ulcerative Colitis—J. A. Bargen, Rochester
Typing Pneumococci—H. A. Reimann, Minneapolis
Bronchiectasis and Lung Abscess—Lipiodol—Everett K. Geer and D. Greth Gardiner, St. Paul
Peripheral Vascular Disease—George E. Brown and Bayard T. Horton, Rochester
Congenital Anomalies of the Kidney—E. A. Boyden, Minneapolis
Primary Tuberculosis in Childhood—X-ray Films—J. R. McNutt, Duluth
Cauterization of Cervix—L. W. Barry, St. Paul
Schick Test—C. A. Stewart, Minneapolis
Technic of Examination of the Blood Smear—C. H. Watkins and F. J. Heck, Rochester
Method of Decompression in Simple Intestinal Obstructions—O. H. Wangensteen and J. R. Paine, Minneapolis
Professional Pharmacy as Applied to the Physicians—Under the auspices of the Inter-professional Relationships Committee of Hennepin County

GENERAL ASSEMBLY

11 A. M.
Presentation of Officers

Davis Method of Prostate Resection, with Moving Pictures—Theo. M. Davis, Greenville, S. C.
Results of Prostatic Resection—H. C. Bumpus, Jr., Rochester
Cystoscopic Prostatectomy—A Further Report—Frederic E. B. Foley, St. Paul

GENERAL ASSEMBLY

Surgical Hall—1 P. M.

Observations on Arterial Hypertension—Ralph Major, Kansas City
Discussion—George E. Brown, Rochester
Discussion—E. T. Bell, Minneapolis

CLINICS

Neurology—E. M. Hammes, St. Paul
Dermatology—Henry Nicholas Klein, St. Paul
Cardiology—C. N. Hensel, St. Paul; Ralph Major, Kansas City
Surgery—Harry Zimmermann, St. Paul
Pediatrics—T. L. Birnberg, St. Paul

FIRST-AID CLINIC FOR MINNESOTA HIGHWAY PATROLMEN

Medical Hall—1 P. M.

Kenneth Bulkley, *Presiding Officer,* Minneapolis
The Equipment Necessary for the First-aid Treatment of Fractures—Roscoe C. Webb, Minneapolis
Cuts and Bruises—J. J. Ryan, St. Paul
Head Injuries in Automobile Accidents—Adolph Hanson, Faribault
Hemorrhages—F. J. Plondke, St. Paul
First-aid Treatment to Common Injuries—Myron O. Henry, Minneapolis

FRACTURE CLINIC—Medical Hall

Demonstration and Discussion of Fractures at the Hip, Elbow and Ankle by the St. Paul Sub-committee of the General Fracture Committee of the American College of Surgeons—A. R. Colvin, *Presiding Officer,* St. Paul

Fractures at the Hip—WALLACE H. COLE and GEO. A. WILLIAMSON, St. Paul
Fractures at the Ankle—VICTOR P. HAUSER and WILLARD S. HOWARD, St. Paul
Fractures at the Elbow—C. C. CHATTERTON and C. CURRY BELL, St. Paul

SCIENTIFIC CINEMA—1 P. M.

Same Program as Tuesday Afternoon

SCIENTIFIC EXHIBITS

Minnesota State Sanatorium
  Demonstrations of Radiologic Examinations of Patients and of the Indians in Minnesota—H. A. BURNS, Superintendent, Ah-Gwah-Ching
Lymanhurst School for Tuberculous Children, City of Minneapolis
  Demonstration of Tuberculosis in Children—F. E. HARRINGTON, Department of Health, Minneapolis; J. A. MYERS, Lymanhurst School, Minneapolis
Minnesota Radiologic Society
  Radiologic Exhibit—B. R. KIRKLIN, President, Rochester; GAGE CLEMENT, Vice President, Duluth; LEO G. RIGLER, Secretary-Treasurer, Minneapolis
The Mayo Foundation for Medical Education and Research. This exhibit is being shown at the meeting of the American Medical Association at New Orleans this year
  Surgery of the Colon and Rectum—FRED W. RANKIN, JOHN DE J. PEMBERTON, L. A. BUIE, C. F. DIXON, A. S. GRAHAM
  Diagnosis and Medical Treatment of the Colon and Rectum—J. A. BARGEN, C. W. BROWN, H. M. WEBER
  The Coronary Circulation—MERRITT B. WHITTEN
  Coronary Occlusion and Myocardial Infarction—A. R. BARNES
  Plastic Surgery. Illustrations before and after treatment with Automatic Projector—GORDON B. NEW, F. A. FIGI
  Diet Research—W. C. ALVAREZ
  An Adequate Diet. A representative will be present to answer questions and discuss various diets—MARY FOLEY
  Ketogenic Diet—Its Use in Idiopathic Epilepsy—H. F. HELMHOLZ and C. J. BARBORKA, Rochester
The Work of the Medical School
  Statistics and Charts—R. E. SCAMMON, Minneapolis
Economics Committee, Minnesota State Medical Association
  Distribution of Population, Wealth, and Physicians in Minnesota—N. O. PEARCE, Minneapolis
Cancer Institute
  WM. A. O'BRIEN, Minneapolis
University of Minnesota
  Fundus Photography. Department of Ophthalmology, University of Minnesota.
  Tularemia. Charts of Distribution in Animals and of Animal Cycles. Wild Animal Specimens, Intermediate Insect Hosts, Pathological Specimens—R. G. GREEN, Minneapolis
  Comparative Pathology. Division of Veterinary Medicine—C. P. FITCH, Chief, St. Paul
Women's Auxiliary
  MRS. JAMES BLAKE, President, Hopkins
Glen Lake Sanatorium
  Methods of Treating Pulmonary Tuberculosis—Staff of Glen Lake Sanatorium, Oak Terrace
  Genito-urinary Tuberculosis—GILBERT J. THOMAS and T. J. KINSELLA, Oak Terrace
  Ano-rectal Lesions in the Tuberculous—W. K. FANSLER and C. K. PETTER, Minneapolis
Minnesota and Ramsey County Public Health Associations
  "The Doctor Sees the Case First."
  Education Material for Distribution in the Field of Tuberculosis and Heart Disease

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of May will be as follows:

May 4—Personal Hygiene—Care of the Body.
May 11—Boils and Carbuncles.
May 18—Mucous Colitis.
May 25—Fibroid Tumors of the Uterus.

AMERICAN ASSOCIATION FOR THE STUDY OF GOITER

The annual meeting of the American Association for the Study of Goiter will take place at Hamilton, Ontario, June 14, 15, 16, 1931.

The program provides for hospital clinics beginning at 7:15 each morning and so-called day clinics from 10 o'clock on. Many surgeons whose names are associated with the goiter problem in Canada and the United States appear on the program. Minnesota participants include Drs. C. H. Mayo, H. S. Plummer and F. W. Rankin of Rochester, and C. O. Rice of Minneapolis.

NORTHWESTERN PEDIATRIC SOCIETY

The annual meeting of the Northwestern Pediatric Society was held at the Town and Country Club, St. Paul, Minnesota, on March 30, 1932. Twenty-four members were present. Dinner was served at 7 P. M. At 8 P. M. the meeting was called to order by Dr. Samuel Amberg, President of the Society.

The following names were proposed for membership: Dr. Emanuel S. Lippman by Dr. S. J. Huenekens and Dr. Charles L. Steinberg by Dr. T. L. Birnberg. Both were elected to membership.

The Treasurer's report showed a balance in the Treasury on March 30, 1932, of $378.20.

The following officers were elected for the ensuing year: Dr. Irvine MacQuarrie, president; Dr. Alexander Stewart, secretary-treasurer.

The invitation to the Society from Herbert Bigelow to visit his Certified Milk Farm was introduced by Dr. Frank Hedenstrom. After some discussion the acceptance of the invitation was left to the discretion of the officers of the Society.

The scientific program consisted of an address by Dr. Dwight E. Minnich, Professor of Zoology, University of Minnesota, on "Some Aspects of Human Heredity," which was extremely well received and instructive, and was freely discussed by many members of the Society.

ALEXANDER STEWART, M.D.
Secretary-Treasurer.

RED RIVER VALLEY SOCIETY

Two North Dakota physicians, Dr. Henry Rudd of Grand Forks and Dr. Russell Gates of Minot, addressed the spring meeting of the Red River Valley Medical Society and its Auxiliary at the Hotel Crookston in Crookston, April 12.

Dr. Rudd's subject was "The Diagnosis and Treatment of Lateral Sinus Thrombosis." Dr. Gates, who is chief roentgenologist of the Northwest Clinic, discussed "Case Histories with Radiological Findings."

Dinner was served.

RICE COUNTY SOCIETY

Dr. M. S. Henderson, president of the State Medical Association, addressed the Rice County Medical Society on "Fractures" Thursday evening, April 7, at the Faribault Clinic rooms.

Other speakers on the same program were Dr. F. J. Savage, Saint Paul, whose subject was "Your Fifteen Dollars," and Dr. E. A. Meydering of Saint Paul, secretary of the State Association, who discussed medical economics.

SOUTH DAKOTA STATE MEDICAL MEETING

The fifty-first annual session of the South Dakota State Medical Association will be held at Langford, South Dakota, June 20, 21, and 22, 1932. An invitation is extended to the members of the Minnesota State Medical Association to attend.

UPPER MISSISSIPPI VALLEY SOCIETY

The winter meeting of the Upper Mississippi Valley Medical Society was held at Brainerd, January 27, with a large attendance and varied program.

The scientific program included a talk by Dr. F. G. Hedenstrom of Saint Paul on "Prophylaxes of Common Contagious Diseases," a moving picture film on "Spinal Anesthesia," a talk by Dr. James K. Anderson of Brainerd on "Treatment of Anal Fissure and Hemorrhoids."

An informal discussion of the Shoulders plan for veterans' insurance was a feature of the evening with Dr. W. W. Will, Bertha; Dr. G. J. Badeaux, Brainerd; Dr. Hedenstrom, and Dr. Anderson leading the discussion.

The following meeting places were selected for the year's meetings: Bemidji for the spring meeting; Little Falls for the fall meeting, which is to be held jointly with the Stearns-Benton County Medical Society; and Brainerd for the winter annual meeting.

WOMEN'S AUXILIARY
Minnesota State Medical Association

President—Mrs. James Blake, Hopkins
Chairman Press and Publicity—Mrs. Glen R. Matchan, Minneapolis
Editor—Mrs. Horatio B. Sweetser, Jr., Minneapolis

ST. LOUIS COUNTY AUXILIARY

On St. Patrick's Day the Duluth Women's Auxiliary were entertained by Mesdames Nicholson, Elias, and Forbes, at a luncheon. The purpose was to raise money for the Auxiliary's milk fund for needy families.

PARK REGION AUXILIARY

The Park Region Medical Society and the Auxiliary met jointly on April 13. The meeting was held at the River Inn, and during the dinner Mrs. James Blake spoke on the work of the Auxiliary. After the dinner the doctors adjourned for a scientific meeting, while a social hour was enjoyed by the Auxiliary. Mrs. C. O. Estrem of Fergus Falls is president of the Auxiliary.

STATE AUXILIARY

County presidents who have not filled out and returned nomination blanks sent them by Mrs. Baxter, should do so immediately. The nominating committee, composed of Mrs. Stephen H. Baxter, of Hennepin County, Chairman; Mrs. R. F. Meyers, Rice County; Mrs. J. C. Rothenburg, Redwood-Brown; Mrs. J. J. Gelz, Stearns-Benton; Mrs. C. K. Williams, Ramsey County, will meet the morning of May 23.

PROGRAM FOR STATE CONVENTION

Monday, May 23, 1932

Technical Exhibits—(Open from 6 until 8 P. M.)

AUDITORIUM THEATER

The Community Hospital—Edward A. Fitzpatrick, Dean Marquette University, Milwaukee
The American Legion—E. V. Cliff, Ortonville
The Public—F. R. Bigelow, St. Paul
The Doctor—Dr. Olin West, Chicago

Tuesday, May 24

Dutch Treat Luncheon—Women's City Club—12:30 P. M.
Greetings—Dr. M. S. Henderson
—Dr. George Earl
Executive Board members and visiting Auxiliary members all welcome
Executive Board Meeting—2:00 P. M.
Auditorium
All reports to be read at this meeting. All doctors' wives welcome.

BANQUET—Lowry Hotel—7:00 P. M.

Wednesday, May 25

GENERAL SESSION—Auditorium—9:00 A. M.

Report of the Executive Board Meeting
Round Table Discussion—"Problems of Everybody"—Led by Dr. O. E. Locken, Dr. S. H. Boyer, Dr. Carl B. Drake, Mrs. R. N. Jones, Mrs. H. M. Blegen, Mrs. J. W. Stuhr
Mental Hygiene—Dr. Louisa Kerschbaumer, St. Peter State Hospital
Echoes from New Orleans Meeting—Mrs. Sherman S. Hesselgrave, St. Paul
Election of Officers

ANNUAL LUNCHEON—Palm Room, St. Paul Hotel

1 P. M.

Music
"Adult Education"—R. R. Price, Extension Division, University of Minnesota, Minneapolis

WOMAN'S AUXILIARY TO THE AMERICAN MEDICAL ASSOCIATION

Tenth Annual Meeting

New Orleans
May 9-13, 1932

Headquarters: Jerusalem Temple, 1137 St. Charles Ave.

Preliminary Program

Monday, May 9, 1932

6:00 P.M.—National Board Dinner and Pre-Convention Meeting (for Board Members only), Orleans Club, 5005 St. Charles Ave.

Tuesday, May 10, 1932

9:00 A.M.—General Meeting. Mrs. Arthur B. McGlothlan *presiding.*
12:30 P.M.—Buffet Luncheon.

2:00 P.M.—Walk through Vieux Carre, with Guides. Starting from the Patio Royale.
8:00 P.M.—General Meeting of the American Medical Association. Auditorium.

Wednesday, May 11, 1932

9:00 A.M.—General Meeting.
12:30 P.M.—*Auxiliary Luncheon. Southern Yacht Club.
2:30 P.M.—Post-Convention Board Meeting. Southern Yacht Club.
New Orleans Country Club
8:30 P.M.—Divertissements in the Garden.
10:00 P.M.—Buffet Supper. Negro Spirituals—Courtesy of the Woman's Auxiliary to the Louisiana State Medical Society.

Thursday, May 12, 1932

9:00 A.M.—General Meeting. Mrs. Walter Jackson *presiding*.
10:00 to 10:50 } Special Round Table Conferences.
11:00 to 11:50 }
12:00 M. —Buffet Luncheon.
1:00 P.M.—*Trip to Oak Alley Plantation; visiting Spillway. Returning at 6 P. M. (Round trip, $2 per person.)
or
2:00 P.M.—*Round-trip over Lake Pontchartrain, via New Bridges. ($2 per person.)
or
2:30 P.M.—*Trip to Versailes Plantation, Battle Field of New Orleans; Docks and Wharves. (Round trip, $1 per person.)
or
2:30 P.M.—*Delgado Museum and City Park; Newcomb Art School and Audubon Park. (Round trip, $1 per person.)
or
2:30 P.M.—*Mayan Exhibit, Tulane University. (Round trip, 25c per person.)

THROMBOPLASTIN-LEDERLE (For Hypodermic Injection) NOT ACCEPTABLE FOR N. N. R.

Because of the lack of evidence for the therapeutic value of thromboplastic substances other than those designed for external use, the Council on Pharmacy and Chemistry has omitted from New and Nonofficial Remedies, preparations of thromboplastin designed for subcutaneous or hypodermic administration. The Council reports that Thromboplastin-Lederle, admitted to New and Nonofficial Remedies, 1923, was stated in the advertising to be intended for both external and internal use; that the firm's thromboplastin proposed for external use has been accepted for New and Nonofficial Remedies; and that, since the firm still markets a thromboplastin solution to be administered by hypodermic injection, this preparation has been declared unacceptable. (Jour. A. M. A., January 9, 1932, p. 143.)

PROCEEDINGS MINNESOTA ACADEMY OF MEDICINE

Meeting of February 10, 1932

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, February 10, 1932. Dinner was served at 7 o'clock and the meeting was called to order at 8:15 by the President, Dr. J. C. Litzenberg. There were fifty-five members present.

Minutes of the January meeting were read by Dr. C. B. Drake, in the absence of the secretary.

The President then called on Dr. William Davis, of St. Paul, to read the minutes of the first meeting of the Academy, which was held on October 13, 1887, with Dr. Edward C. Spencer as Secretary. Dr. Davis presented the original copy of these minutes to the Academy and a motion was carried that they be placed in the permanent records of the Academy with this meeting of February 10.

The President announced the death of Dr. John Fulton, one of the oldest and best loved members of the Academy, and appointed a committee consisting of Dr. John Brown, Chairman, and Drs. S. M. White and J. S. Gilfillan, to draft resolutions on Dr. Fulton's death.

The following scientific program was given:

Dr. Kenneth Bulkley (Minneapolis) read his inaugural Thesis entitled "The Rôle of Oxyuris and Trichocephalus in the Etiology of Appendicitis." This was illustrated with numerous lantern slides showing serial sections of appendices. (To be published later in Minnesota Medicine.)

DISCUSSION

Dr. W. R. Ramsey (St. Paul): During the War I was in France for a year and a half with Dr. Park and our work was among the child refugees. Dr. Park came to the conclusion that these parasites were normal, at least in French children during the war; he found practically none of the children of that class that did not have pin worms. The very fact that it is so difficult to rid these children of these worms suggests in all probability that the appendix is involved and this may explain the recurrences of the worms. You think you have gotten rid of them and then so frequently they later recur. This may be the explanation.

Dr. A. Schwyzer (St. Paul): I think nearly all of us are a little stunned to see that the oxyuris on close examination should be so frequently found. I recall one little girl of 7 years. On opening her appendix, these oxyuris were so thick that they looked just like fur on the inside of the appendix. Still, the percentage in Dr. Bulkley's cases seems to me to be rather large. From now on we shall examine the removed appendices still more carefully than before. We always examine the appendix and make sections; but of course to make serial sections of the whole appendix is too much to ask of the laboratory man. It may be that we have not encountered oxyuris more often because we were not impressed with the necessity of looking very exactly for even young ones. Trichocephalus dispar I have not seen. I should not have said anything on this subject but for one thing which I recently read in the Zentralblatt fur Chirurgie, where it was urged to section the appendices longitudinally. The appendix is rolled up tightly and is then sectioned longitudinally. In this way the microscopic examination is greatly simplified and overlooking areas of localized trouble is much more easily avoided.

Dr. A. E. Benjamin (Minneapolis): I want to mention a case similar to the corollary by Dr. Bulkley in his paper. I recall one patient about eight years ago who had worms and who had had various treatments, but with no results. Her appendix was always tender and I thought perhaps a good way to get rid of the worms was to take out the appendix. She has had no further trouble since the operation. We found numerous worms in the appendix. I believe this is of more common occurrence than we think; the trouble is not cured by the usual treatment because the worms are in the appendix.

Dr. J. C. Litzenberg (Minneapolis): It would not have been necessary to go back to the Zentralblatt for that method, for in the *American Journal of Obstetrics and Gynecology,* June, 1920, that method was given in the making of sections of the whole Fallopian tube, which is comparable to the appendix.

I had a very unusual case where there was tuberculosis of the uterus, vagina, and tubes. I coiled them all up together and found the lesions in the coiled specimen clear from the vulva to the end of the tube. It is a good method.

Dr. A. E. Wilcox (Minneapolis) reported the following case of Extraperitoneal Cyst:

The patient, Mrs. C. M., age 39, was admitted to Eitel Hospital at 2 a. m. August 20, 1931. The present illness commenced on August 16, 1931, with uterine bleeding, at first slight in amount. The following day the bleeding ceased, and then continued irregularly, being bright red and, at times, dark clots only. The patient felt weak, with pain low in the back on both sides. The day of admission she experienced quite severe pain in the left lower quadrant of the abdomen. The pain was intermittent and was referred down the inside of the left thigh.

She had been operated for ectopic pregnancy, right side, in 1927. Her last menstrual period was May 25, 1931.

Examination showed a well-nourished woman of about the age given, complaining of severe pain on the left side. Pelvic examination showed marked tenderness and resistance in the left side, but no definite outline of any tumor could be made out, and mobility of the uterus was questionable on account of the pain. The cervix was negative.

Diagnosis was acute abdomen—(1) ectopic pregnancy; (2) ovarian cyst, possible torsion of pedicle.

Operation: On August 20, 1931, at 10:50 a. m., under spinal anesthesia (200 mgm. N_2O) a midline incision was made. There was no free fluid in the abdomen, but there were dense adhesions of the large and small bowel to the right cornu of the uterus and right broad ligament. A cyst about the size of a large lemon was found on the left side with its pedicle and the left tube twisted. This was located deep in the pelvis. A cyst about the same size was found on the right side. Adhesions of the large bowel were relieved and the serous covering of the bowel stitched with dulox sutures. Both cysts were removed without disturbing the other appendages. The right side had been operated (previous history). The wound was closed with plain for the peritoneum, chromic for the fascia, single layer reinforced with three or four interrupted sutures. Silkworm was used for the skin. The postoperative period was quite uncomfortable for four or five days, more so than usual, the patient having considerable distention, nausea, and repeated emesis; but from the fifth day post-operative until discharged her record shows nothing unusual and her temperature was normal. She was discharged Sept. 1, 1931, apparently well.

On September 8, 1931, she reported that since leaving the hospital backache and insomnia had been marked and recently she had pain in the left lower quadrant. In reviewing the case, I found she had complained some of pain in this area while in the hospital.

Examination showed the abdominal wound healed. On palpation a feeling of resistance was noted low in the left lower quadrant, and on vaginal examination not only a resistance to the left, but a palpable mass occupying a position to the left and downward from the uterus, which was smooth, slightly movable, and in size comparable to a four-months pregnant uterus. There had been no menstrual bleeding, but she reported some vaginal discharge. After the patient had urinated, the vaginal examination was repeated and the same findings were present, namely, a mass in the position of the uterus extending to the left and downward. Other examinations were negative.

On October 26, 1931, she reported that she had had one normal menstrual period. The same physical findings were present in regard to the mass. The leukocyte count was 12,000. No definite diagnosis was made, and exploratory operation advised. A scout X-ray film of the pelvis and mass was made, with negative deductions.

On November 6, 1931, under spinal anesthesia, a midline incision was made, dissecting out the previous operative scar. Upon opening the peritoneum above the mass, the omentum was found adherent to the parietal peritoneum. There was no free fluid in the abdomen. The left ovary appeared normal (evidently the cyst removed at the previous operation was of para-ovarian origin). The tube on the left side was distended with fluid (hydrosalpinx). This tube was removed. After a few adhesions to the surrounding structures were separated, the uterus could be brought up and inspected and it appeared to be normal although there were some adhesions on the right side.

The bladder was pushed over to the right side and backward, and the mass which had been felt previous to operation proved to be extraperitoneal and occupied a position to the left side of the bladder, in front of the uterus, and reached down to the symphysis pubis. The peritoneum was then closed above the mass, the abdominal muscles separated from the peritoneum, and the upper part of the mass came into view, which was somewhat regular, giving an impression of fluctuation. A line of cleavage was found and enucleation started. On the outer and anterior and also on the mesial side of this mass enucleation was more difficult as the adhesions were more dense. At one time the question of this mass being an obstructing diverticulum of the bladder was considered, but, inasmuch as it was extraperitoneal, this theory was discarded. A moderate sized needle was used to aspirate the mass and hemorrhagic fluid was obtained (a small amount for culture). Enucleation was then continued and eventually the mass was removed. It was about the size of a normal kidney and much the same shape. A small rupture occurred on its outer side during the process of enucleation, but this was clamped, no serious hemorrhage was encountered, and no definite connection of this mass to the other structures was found, it being enucleated en masse. The peritoneum was then closed with plain and a Penrose tube placed into the extraperitoneal bed from which the mass had been enucleated. The wound was closed with tier sutures, silkworm stay sutures, and clips for the skin. The postoperative recovery was progressive. The patient left the hospital November 19, 1931, and has remained well since.

Pathological report on specimen: Several sections were made of the wall and all show a rather uniform structure. The outer portion is composed of rather dense connective tissue with diffuse and focal infiltration of lymphocytes, plasma cells and an occasional neutrophile. The inner lining is covered with a membrane composed of red blood cells in various stages of disintegration. Just beneath this there is a band of cells showing marked phagocytosis of hemosiderin. No evidence of malignancy is seen. There are no structures resembling endometrial glands present. The sections have the appearance of a fibrous reaction to an escape of free blood into the tissues. Diagnosis: encysted hematoma. (Wm. A. O'Brien, Pathologist.)

DISCUSSION

Dr. J. L. Rothrock (St. Paul): It was my privilege to operate on a retroperitoneal cyst a little more than a year ago. These tumors of various kinds are not at all uncommon. In my case the tumor lay behind the cecum. At first I thought it might be a renal tumor but after further investigation we decided it probably was not. I thought of hypernephroma but it did not extend up as far as the kidney. I then thought it might be a cyst of the ovary with adhesions.

At operation we found this tumor was intraperitoneal, and lay behind the cecum. I divided the peritoneum over the cyst and then, to my surprise and satisfaction, it was the simplest thing in the world to enucleate it. It was attached by no blood vessels and had no pedicle. There was very little bleeding except where we divided the peritoneum over the cyst. It measured 15 by 12 by 9 cm., or a flattened oval in shape. It seemed to have a fluid which was dark in color and which was described as greyish brown. When it was opened, we found there were low papillary growths 1 cm. in diameter in one area of the cyst wall. The cyst wall was rather thin and showed nothing in particular. On microscopic examination this was found to be adenocarcinoma. This woman was 31 years old and the only symptom of which she complained was this tumor. A year after the operation there was no recurrence. I have not recently heard about her, but have written to inquire how she is.

One thing which makes me think the prognosis may not be so bad was that at no place had these papillary growths penetrated through the capsule. There were not many lymphatics leading from it. The chances for permanent cure were perhaps not so bad in that case.

Dr. A. E. Benjamin reported a case in connection with the paper on "Nasal Suction Treatment of Postoperative Vomiting, Pain and Dehydration." (To be published in Minnesota Medicine.)

This patient is a young single man 22 years of age, five feet six and one-fourth inches tall, weight 138 pounds, and is employed as an electrician. His health has been fairly good in the past with the exception of having had children's diseases; infection of the left hand and wrist in 1927, which required lancing and drainage; pneumonia in 1928; and in November, 1931, he had another slight infection of the left wrist. He has had a few attacks of tonsillitis. His general habits are good. He smokes about half a package of cigarettes a day. His family history is essentially negative.

On November 15, 1931, at about 8 a. m., while out hunting, he carelessly put his No. 22 (long) cocked revolver back into the holster on his right side. The revolver went off and the bullet diagonally entered the lower right quadrant of the abdomen. He at once drove his car a mile and a half to a farm house for help. He was taken to Dr. Arey at Excelsior, who gave him a hypodermic of morphin and first aid treatment, and he was then rushed to the Northwestern Hospital.

X-rays of the abdomen, taken on the day of admittance, show a somewhat diffuse haziness over the entire abdomen. There is one area of density at the level of the crest of the right ileum which simulated a metallic foreign body. Conclusions: Definite evidence of fluid in the abdomen. Determination of the presence of a metallic foreign body is not definite due to a movement and slow exposure of the portable machine.

The patient seemed in fair condition, pulse 80, temperature 97.4°. Although there was a rigid abdomen, especially on the lower right, he complained of little pain or discomfort. There was dullness in the lower abdomen. Upon evacuation of the bladder, the urine contained no blood. He was not in distinct shock so an operation was determined upon and performed three hours after the accident.

Under local, gas and ether anesthesia a right rectus incision was made just inside and above the anterior superior spine. The omentum was protruding through the muscle bullet wound. The abdomen contained much blood and clots, and the contents of the bowel had escaped and mixed with this. Saline solution with a suction was used to wash out the fecal matter from the abdominal cavity. The ileum was injured and punctured in nine places. The punctures and rents occurred in various places for about three feet along this part of the bowel. One area consisted of an injury to the mesentery for about 2 inches, causing considerable hemorrhage in the abdomen. At this point the bowel wall was not punctured. At a second area 2 inches in extent the bowel wall was ripped open on the side opposite from the mesentery and near the end of this area three small punctures existed near each other, two of them within ¾ of an inch, about the size of a slate pencil. The bowel was punctured by the bullet in other areas about the same size. The cecum was injured about 4 inches upward along the ascending colon but the wall was not completely severed. The rest of the intestine was examined up to about the middle of the jejunum, as well as the sigmoid, rectum, and ascending colon, but no injury was found. The iliac vessels seemed to be intact and apparently there was no bleeding from that source. The bullet was not found. It may have entered the bowel and been later evacuated.

All the raw and lacerated areas were carefully stitched with Dulox, turning the raw edges in. The circulation in one area where the bowel had been greatly lacerated was somewhat impaired, but this area was stitched in such a way that the remaining portion seemed to be well supplied with functioning blood vessels. All the areas involved were brought within a small space just below the incision, the omentum covering these areas, and four Penrose drains extended into the pelvis below these injured coils. The abdomen was closed with chromic No. 1 with the muscle and peritoneum included. Four dermal stay sutures tied over a roll of gauze were put in the inner side of the incision. The skin was closed with chromic No. 0.

The patient stood the operation very well. There seemed to be very little shock. On the second day after the operation the patient's abdomen became distended and he complained of distress and pain in the back, and he had eructation of gas. A Levin catheter was then passed through the nasal cavity into the stomach and this was attached to a tube connected with an inverted suspended bottle filled with water. This bottle was connected to a bottle on the floor to permit continuous suction to remove the gas from the stomach. I have used a similar plan on cases in the past but was not able by that method to measure the gas removed or the fluids absorbed. Dr. Wangensteen, of the Surgical Department of the University Hospital, has employed a more elaborate method whereby the gas removed and the fluids absorbed can be measured. His plan I adopted in this case, with marked success, as will be noted on the symptom chart herewith. (The use of this continued suction apparatus was shown on the screen, as well as other charts with symptoms and progress.)

The urine was negative upon admittance to the hospital, but on the third day there was a slight trace of albumin, indican, many mucous threads, occasional epithelial cells, and two to six pus cells. On the fifth day albumin was still present and a rare hyaline cast, with ten to fifteen pus cells. On the twenty-first day there was again a slight trace of albumin.

The day after his operation his temperature went up to 102.8°, pulse 110, and respirations 28. For the next five days the temperature fluctuated between 100° and

102°, after which time it gradually declined so that on the 10th day it was normal and remained about normal until he left the hospital. Up to the tenth day his pulse was between 85 and 100, but after that day it remained practically normal. There were no respiratory complications.

This case demonstrated the benefits derived from the continuous suction apparatus, which has the following advantages: (1) relieves pain; (2) necessitates fewer hypodermics; (3) is a distinct psychological benefit; (4) prevents vomiting; (5) permits the patient to drink freely; (6) increases the comfort of the patient; (7) permits more rest and sleep; (8) reduces the temperature; (9) lessens intra-abdominal tension; (10) decreases the possibility of spreading peritonitis; (11) occasions earlier bowel function; and (12) hastens recovery and reduces mortality.

DISCUSSION

Dr. Rothrock: Did I understand Dr. Benjamin correctly, that he did not pass the tube into the duodenum?

Dr. Benjamin: It was put just into the stomach. I have some X-ray slides which may show that, although possibly not very clearly.

The meeting adjourned.

R. T. LaVake, M.D.
Secretary.

PROCEEDINGS MINNEAPOLIS SURGICAL SOCIETY

Meeting of March 3, 1932

The President, Dr. J. Frank Corbett, in the chair.

The following scientific program was given:

Dr. Roscoe C. Webb presented the specimen and reported the case of a girl fifteen years of age first seen at 8 o'clock in the evening of Tuesday, June 24, 1930, with pain in the right lower quadrant of the abdomen which was cramplike and very severe. Her father had returned from a successful fishing trip on Saturday, four days previously, and she had eaten fish on Sunday and Monday. At two o'clock in the afternoon, six hours previously, while riding in an auto she began to have pains in the lower abdomen on the right side and the severity gradually increased until at the end of six hours the pains were very severe and the doctor was called to see her.

Her past history was unimportant. There was no previous history of gastrointestinal disturbance. She had had pyelitis four years previously.

The general physical examination was that of a well-developed girl who was entirely normal except for the abdomen. There was marked tenderness in the right lower quadrant extending well down toward the pelvis. There was marked rigidity throughout this tender area but no distention. The temperature was 100°, pulse 72, and respirations 20. The white blood count was 13,700 and the differential showed 69 per cent polymorphonuclears, 29 per cent small lymphocytes, and 2 per cent large mononuclears. The urine was normal.

The patient was operated upon by Dr. Webb at Northwestern Hospital about nine hours after the onset of symptoms as follows: Using nitrous oxide and ether anesthesia, a four-inch lower right rectus incision was made. On opening the peritoneum the small intestine which presented was found to be inflamed and on searching for the appendix turbid fluid was found in the right lower quadrant and also in the pelvis. The fluid was not walled off. A swab of the fluid was sent to the laboratory for smear and for cultures. The appendix was readily found and delivered and was moderately long and showed evidence of a previous inflammation but was not acutely inflamed at the time. The appendix was ligated and the stump was cauterized and inverted. A search was made for the cause of the peritonitis and the patient was placed in the Trendelenburg position after aspirating the fluid and the pelvic organs were examined visually. At the same time, about the level of the brim of the pelvis, he saw what appeared to be about one-half inch of number one catgut lying on the surface of one of the loops of intestines and on closer examination he found that this was lying on a Meckel's diverticulum which was only slightly inflamed near its tip. The Meckel's diverticulum was about the size of the thumb of an ordinary rubber glove and the object on the diverticulum was a fish bone which had perforated the diverticulum about one-half an inch from its tip with the sharp end sticking out and the larger end of the fish bone still within the lumen of the diverticulum, thus permitting a constant escape of the intestinal contents. The diverticulum was ligated and removed and the stump inverted with a double row of Lembert catgut sutures. A Penrose drain was placed in the pouch of Douglas and brought out at the lower angle of the wound. The wound was closed in tiers using dermal for the skin.

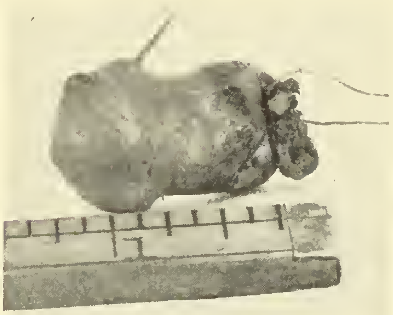
Convalescence was quite uneventful. The maximum temperature was 101°, pulse 108, and respirations 24. The drain was completely removed on June 29, five days after operation. The patient was discharged from the hospital on July 11, 1930.

In the February, 1932, issue of the *Annals of Surgery*, under the Transactions of the Philadelphia Academy of Surgery, meeting of October 5, 1931, Dr. Walkling reported the case of a boy eight years of age admitted May 5, 1930. The patient had eaten fish three days before and on operation an abscess was found in the center of which there was a Meckel's diverticulum, perforated by a fish bone. Recovery occurred. Dr. Walking remarked that this condition was reported only once before. (Blanc, H.: Bull. et Mem. Soc. de Chirurg. de Paris, Vol. xxi, p. 378, 1929.) This patient, a man forty-one years of age, was operated upon in 1898. The patient's symptoms had begun ten days previously. After five days' observation the patient was operated upon and a hard fibrous mass was found and when freed was found to be a Meckel's diverticulum, which was resected. It was found to have a fish bone in its wall. Recovery was uneventful.

A woman forty-five years of age was reported in April, 1900, by Piquand and Grenet in the Bulletin and Memoirs of the Societe anatomie de Paris. She had had abdominal pains for one year, and eight days before admission her symptoms became acute. There was a large tender mass in the abdomen and she was observed for five days, at the end of which time she died in coma. There was a localized abscess, in the center of which was a Meckel's diverticulum perforated by a fish bone.

Hagler and Stewart, in the *Journal of the American Medical Association,* May 15, 1920, reported the case of a man aged thirty-nine years who had had abdominal pain for two days and the symptoms suggested acute appendicitis. On operation a Meckel's diverticulum was found in an omental mass and a fish bone was found perforating it. It was necessary to resect about six inches of the ileum. A general peritonitis developed and the patient died six days after admission. These authors stated that they had found reference to but two other cases of perforation of Meckel's diverticulum by a fish bone.

Dr. Webb stated that, in his search of the literature, he had been able to find but four other case reports of this rare condition and it would appear that this series of five cases is the largest number thus far collected. The diverticulum described by Meckel occurs in a very small percentage of cases. The percentage of humans who swallow fish bones is also small. However, when one operates for acute appendicitis with perfectly good reasons and a normal appendix is found, the diverticulum of Meckel should be kept in mind and a search made.



Meckel's diverticulum showing the fish bone in the position found at operation (actual size).

Dr. E. A. Regnier reported the following case of "Carcinoma of the Lower Ileum with Complete Intestinal Obstruction of Three Weeks' Duration":

The patient, Mr. C. G., male, aged fifty-two, a railroad brakeman, was admitted to General Hospital August 4, 1931. (Discharged Oct. 17, 1931.)

He had had intermittent cramp, colicky pains in the abdomen of several months' duration, more severe the past three weeks. There had been nausea and vomiting daily for the past two weeks; and he had had no stools for the past two weeks.

The onset of the illness had been gradual. The colicky pains began in the right side of the abdomen and radiated to the lower abdomen, and eventually the colic involved the entire abdomen. The patient said he had been hearing gurgling and tinkling sounds accompanying the colic. Under advice of his physician he took nothing but liquids by mouth, and also took daily enemas. The first week of his illness the stools were very small, and there had been none for two weeks. There had been no bloody stools.

He had had an appendectomy in 1929; otherwise his past history was non-essential. Gastrointestinal studies made in 1929 were reported normal.

The physical examination showed a white male, much undernourished, who appeared to be in very severe pain. The pupils were equal and reacted. The tongue was furred. Blood pressure was 138/86. The examination was entirely normal except for the loss of weight, marked abdominal distention, tympany throughout the abdomen, and loud metallic sounds audible on auscultation over the abdomen at the acme of peristalsis. Peristalsis was visible over the entire lower abdomen.

After attempting to determine the origin of the obstruction and partially replenish the fluid loss in this patient, the abdomen was explored under spinal anesthesia on the 8th day of August. There was a large amount of free fluid in the abdomen. The entire ileum was distended to a diameter of about four inches and the wall was markedly thickened. Due to terrific intra-abdominal pressure, several loops of the bowel had herniated through the foramen of Winslow. There was a constricting mass about five centimeters long and three centimeters in diameter completely obstructing the ileum about six inches above the ileocecal valve.

Laboratory findings on his admission to the hospital were: Wassermann negative. Urine showed a faint trace of albumin. Blood: Hb. 90 per cent, R. B. C. 4,500,000, W.B.C. 9,000; blood chlorides 396 mgms. per 100 c.c.; blood urea 22.2 mgm.; Van Slyke 62 per cent. Occult blood was found in two stool specimens.

The patient developed bronchial pneumonia following the first operation. He was very toxic for ten days. The enterostomy functioned perfectly and the patient was able to eat well and gained in weight.

Under general anesthesia the patient was operated on the 22nd day of September, at which time the terminal fifteen inches of ileum, the entire cecum and ascending colon to the mid-transverse colon was resected and an end-to-end anastomosis was done between the ileum and transverse colon.

Convalescence was very uneventful. The patient gained in weight rapidly and at the present writing has regained his normal weight.

Pathologist's report: Specimen consists of loops of bowel as described above. Six inches above the ileocecal valve the ileum was constricted and on opening shows a villous mass filling the lumen for 5 cm. An enlarged node is present in the mesentery. The ileum above the stricture measured 15 cm. in circumference.

Microscopic picture: The tumor has a papillary structure and consists of glandular tissue. There is dense fibrosis of submucosa and serosa which contains nests of deeply staining epithelium and atypical glandular structures. The muscular coat of the gut is enormously hypertrophied.

Diagnosis: Papillary adenocarcinoma of the terminal ileum.

The significant features of this case are (1) the duration of complete obstruction without fatal outcome, and (2) the rarity of the lesion.

In 17,000 autopsies at the University of Minnesota there were only five cases of carcinoma of the ileum. The diagnosis of obstruction in this case was very obvious. X-ray is of no help in locating these lesions and is usually contraindicated. In complete obstruction X-ray is of much help in ruling out other lesions, namely in the colon or stomach.

Rankin states that about three per cent of cancers of the intestinal tract occur in the small intestine. In a twenty-year period in the Mayo Clinic only fifty-five cases of cancer of the small intestine were reported. This type of tumor must be differentiated from the so-called carcinoid tumors of the small intestine, 80 per cent of which are benign.

Ewing divides cancer of the small intestine into those developing from carcinoid tumors, or from polyposis, or from true localized adenocarcinoma. From a review of the literature, the prognosis is poor. The Mayo Clinic reports no three-year cures.

Dr. A. F. Bratrud reported a case of "Meckel's Diverticulum in a Strangulated Hernia."

The patient, Mrs. A. M., was a female, aged 50, Swedish, occupation housewife. Her father and mother are dead of unknown cause. She has one brother, aged 63, living and well, and one sister living and well.

This patient was first seen by Dr. Bratrud on July 7, 1930. She had been seen ten days previously by Dr. Wahlquist, Minneapolis, for pain in the lower abdomen accompanied by nausea and vomiting. The pain began in the right lower abdomen and became cramp-like in character. She had been nauseated during the entire period of ten days. She vomited daily with the exception of three days. During the past four or five years she had been wearing a truss for a hernia in the right lower abdomen. Her appetite had always been good; bowels were regular. The urine was normal. Menstruation began at the age of thirteen, and had been regular up to the persent time, with the exception that now they occur every five or six weeks. She has had six children, three of which died during infancy; the other three are living and well. Since the present attack began ten days ago she has been constipated, but the bowels moved with an enema. She had had no night sweats.

Examination is that of a well-nourished and well-developed woman about fifty years of age. Her blood pressure is 153/90; pulse 95. The examination of the eyes, ears, nose and throat is normal, with the exception that her hearing is not very acute. There is no adenopathy and no enlargement of the thyroid. Breath sounds were normal in both chests, with the exception of a few moist râles at the left base. The heart is normal in outline but there is a soft systolic murmur at the apex. The abdomen is rather pendulous, with moderate distention and with a mass slightly larger than a hen's egg in the right inguinal region. This mass is very hard and firm and moderately tender to pressure. There is no fluctuation to be determined. It is not reducible. There is dulness in this mass on percussion. There is no other mass to be felt in the abdomen.

The reflexes were normal, and all motor function was normal. Urinalysis showed a faint trace of albumin, with a very slight reduction for sugar, and a large number of pus and red cells.

A diagnosis of strangulated right inguinal hernia was made on this patient when seen by Dr. Wahlquist on June 29, 1930, but the patient refused operation continually until July 7, 1930.

Operation was performed on July 7, 1930, at which time there was a mass 2.5 × 0.5 inches in length in the right inguinal region. This was very hard and very firm. Under local anesthesia, infiltration being made at a distance from the mass, a right inguinal incision was made. There was a peculiar greenish discoloration of edematous tissue surrounding this mass. It was very difficult to separate the tissues down to the mass and determine the character of same. A Farr spring retractor was placed in the wound and in so doing one of the arms of the retractor slipped and punctured the mass. There was an immediate discharge of gas which had a fecal odor. Wet packs were at once placed around the mass and the wound was washed with S. T. 37 solution. An opening was made above the inguinal incision in order to observe better the character of this mass, as this woman did not have a complete intestinal obstruction at any time. The incision was gradually brought to the neck of the mass, and at that point there was a gangrenous area which involved a loop of the ileum and part of its mesenteric attachment. A resection of the ileum and part of the mesentery which was gangrenous and an end-to-end anastomosis were performed. A number eight rubber glove was packed with gauze and this was placed within the abdominal cavity and the wound was strapped. No sutures were placed in the wound.

Pathological report: The specimen which was removed consisted of a large piece of tissue matted together with adhesions. The organ removed is hollow and lined with a folded mucous membrane. This is either intestine or a diverticulum from the intestine. There is a hard area which is being sectioned. This tissue shows a necrosis which has destroyed the organized tissue near the serous coat. Many pus cells and eosinophiles are present. The epithelial layer is made up of glands consisting of high columnar cells, containing mucus. I can't tell whether or not it is intestine or a diverticulum. (Floyd Grave, pathologist.)

Postoperative treatment consisted of normal saline solution intravenously, pantopon whenever necessary for pain, and ergot twice daily. Perfringens vaccine was given intramuscularly.

There was never any very severe reaction following the operation, but there was a very profuse purulent discharge from the wound. There was no nausea, vomiting, distention, nor pulmonary complications following the operation. By July 13, 1930, all of the gauze was removed from the glove and the glove was loosened. This was removed two days later. On July 18, 1930, there was still quite profuse drainage from the wound, but it was healing nicely and the edges were very clean. On August 4th, the wound was practically healed. There was practically no drainage at this time except from the granulation tissues. The bowels had been moving regularly since the date of her operation. She was discharged on August 4, with no evidence of a hernia. She was last seen September 10, 1930, at which time the wound was very well healed and there was but a very slight bulging in the operative wound. This could not be interpreted as a recurrent hernia. She has been free from any symptoms since her operation.

It was impossible in this case to determine whether this was a Meckel's diverticulum in an inguinal hernia, or a Richter's hernia. It was impossible, while making the dissection, to determine whether this was a hard tumor or a tumor consisting of a hollow viscus, until the mass was punctured by a retractor.

Dr. Bratrud wished particularly to emphasize the nice healing which results from this form of treatment of wounds and the complete absence of any reaction in the tissues surrounding the wound following an operation where it is so treated.

DISCUSSION (OF PRECEDING CASE REPORTS)

Dr. A. T. Mann asked how large the mass was in Dr. Bratrud's case?

Dr. Bratrud stated it was about two and a half inches in diameter and round.

Dr. Mann stated that these Meckel's diverticula are very interesting to him; he had seen four cases. There were several points he wished to bring out. In the first place it is almost impossible to make a diagnosis correctly before operation; and no one really knows that he has a Meckel's until he sees it. Dr. Mann suggested that in Dr. Bratrud's case it may have been bowel.

Dr. Mann further stated that a Meckel's diverticulum is subject to all the inflammations that the appendix is and is much more difficult to diagnose than trouble with the appendix. Besides that, it has all the troubles of the bands and cords and twists causing obstruction; so that when there is inflammation in a diverticulum one is quite likely to get more or less obstruction with it also. In regard to the degree of inflammation, one may get everything up to perforation in a Meckel's, and Meckel's occurs in one or two per cent of all people. For diagnosis, a Meckel's is much more free than the appendix and on account of its freedom and its larger size and poor blood supply, it is more apt to have a more rapid perforation than the appendix. The diagnosis is more difficult to make because it can be in more places than the appendix can. One knows just about the range an appendix can have. Then, too, if there is inflammation it is much less likely to be walled off than the appendix, so that, unless the Meckel's is pretty much up toward the midline, one can't even make a guess that it is a Meckel's which may be inflamed. R. M. Harbin, of Rome, Georgia, was formerly abroad with him, and Dr. Mann stated that he gets reports from his hospital each year. Dr. Harbin reported a year or so ago on over 2,600 cases of operations, and stated that the greatest cause of death was appendicitis (25 per cent), and the next greatest was obstruction of the bowel (16 per cent); but the point which interested Dr. Mann was that 10 per cent of these obstructions were due to Meckel's diverticula. A Meckel's, then, can give one the obstruction and, in addition, all the troubles that one encounters with the appendix, including foreign bodies; and the foreign bodies much more easily get into the Meckel's diverticulum. Dr. Mann said he has seen pins and also grape seed in the appendix and cited the case of one man who had eaten a whole basket of grapes at one sitting and at operation the acute appendix was found full of grape seeds.

Of late more cases of Meckel's are being reported. Peptic ulcers, similar to those of the stomach and duodenum, have been reported. In some of these ulcer cases, heterotopia has been found and microscopic sections of the mucous membrane have shown mucous membrane identical in structure with that of the stomach. Some of these cases have been discovered because of large hemorrhages and melanotic stools. In other cases the hemorrhage is smaller but, because of the thin-walled gut, they lend themselves rather readily to perforation and extravasation.

In conclusion, Dr. Mann stated that the diagnosis of Meckel's is difficult until one gets into it; that the dangers are very much greater than those of appendicitis; and, if it is a case of inflammation, the perforation is much more rapid. There is more apt to be a spreading peritonitis and these latter cases result in more deaths than similar cases of appendicitis. Besides, they are often accompanied by intestinal obstruction, with strangulation, necrosis and gangrene. And in a considerable number, the necessity for an intestinal resection adds materially to the dangers.

Dr. S. R. Maxeiner said Dr. Webb's case of foreign body in a Meckel's diverticulum reminded him of a case he reported at the Western Surgical Association, of a patient who came to St. Mary's Hospital with a very acute abdominal complaint which was not entirely typical of appendicitis. At the onset of the complaint the patient was in North Dakota and was not seen by Dr. Maxeiner until three or four days after the beginning of the attack. On opening the abdomen, the appendix was found not to be the cause of the attack, but the sigmoid with an extremely redundant mesentery was lying on the right side of the pelvis. A fairly large mass presented which, when opened, was found to contain an abscess in the center of which was a toothpick lying freely in the abscess cavity and which had penetrated a diverticulum of the sigmoid. The abscess was largely on the right side because of the position of the sigmoid.

Dr. Maxeiner also reported a case of obstruction from Meckel's diverticulum operated upon by him at the Minneapolis General Hospital. He also encountered an acute diverticulitis in which the diverticulum was removed, and one case of diverticulitis had been encountered in which he had done no operation whatever because it appeared merely as a bulging area on the side of the ileum with free opening into the bowel and was causing no complaint.

Dr. O. H. Wangensteen stated that these were very interesting cases, and that the comment that he desired to make concerned only the features of bowel obstruction. The most outstanding consideration in bowel obstruction is the appalling mortality. In reported statistics it appears that the risk borne by one patient with acute intestinal obstruction equals that shared by ten patients having acute suppurative appendicitis. Whereas the potential danger to life of a perforated duodenal ulcer would appear to be far greater than of mere obstruction to the continuity of the bowel, the actual danger incurred by the patient with bowel obstruction as judged from the general mortality of these two disasters is twice as great.

The danger is largely that of delay. In a hospital whose resident and attending staff are "obstruction-minded," postoperative obstructions are early recognized. The complaint of these patients is usually that of "gas pains," which often go unheeded until vomiting occurs. The diagnosis of acute intestinal obstruction should be one of the easiest of acute disorders of the abdomen to recognize. If one will determine the presence or absence of *intestinal colic* by noting whether loud intestinal borborygmi are heard with the stethoscope at the acme of the pain, he has gone far to establish a diagnosis. The other colics of the abdomen, such as biliary, appendiceal, or renal colic, do not present loud intestinal noises, significant of increased peristaltic activity, at the height of the pain. When the presence of intestinal colic has been determined, it only remains to say whether this is acute intestinal obstruction, enterocolitis, food poisoning, abdominal allergy or simple "belly-ache," and on the general symptoms such as nausea, vomiting and diarrhea, a good appraisal or evaluation of the intestinal colic can usually be made.

Dr. Wangensteen said there were two therapeutic agents, the use of which he wished to discuss briefly. One is the employment of saline. It should be remembered that saline exhibits the virtues of a specific only in high intestinal obstruction. In low intestinal obstruction it is in no sense a specific, its greatest worth lying in combating dehydration. Dr. Wangensteen stated that it was not his observation that patients with low obstruction were improved very much as operative risks by a prolonged delay for saline administration. Only when the patient is badly dehydrated and the X-ray film indicates that the bowel distention is not great can prolonged delay be justified.

Dr. Wangensteen stated that since August, 1931, he had employed nasal catheter siphonage for decompressing the bowel in simple obstruction of the intestine without strangulation features. Of the seven cases seen since that time, all but one were successfully decompressed with nasal suction alone without operation. The third case was subjected to enterostomy after 12 hours suction when no appreciable diminution of the distention was visible on the X-ray film, and he convalesced smoothly. Since then Dr. Wangensteen stated that he had succeeded in decompressing a case exhibiting even more marked obstructive features. In the case in which enterostomy was done, the catheter could not be gotten into the duodenum.

The rationale upon which a decompression can be effected by this method, Dr. Wangensteen explained, resided in the fact that the chief source of intestinal gas is swallowed air. After the decompression is accomplished, in the absence of an intrinsic obstruction in the intestine, the intestinal continuity is automatically established.

Resection and primary anastomosis in the presence of a strangulated non-viable gut, Dr. Wangensteen felt to be a hazardous procedure. In such instances he thought it much wiser to exteriorize the devitalized bowel and establish the continuity by a secondary anastomosis. The combined risks of these two procedures he felt would not approximate the risk borne by the patient when a primary resection was done. In his monograph on bowel obstruction, Wilhelm Braun, of the Friedrichshain Hospital in Berlin, writes that their mortality in strangulated external hernia with non-viable gut in which resections were done was over 50 per cent.

Dr. J. A. Johnson stated that about ten years ago, in 1922, he first became interested in Meckel's diverticula. At that time he collected three cases in which a Meckel's diverticulum was the cause of intestinal obstruction. Since that time he had had no one other case. He felt it was a very interesting subject and he appreciated hearing the cases reported tonight. In connection with Dr. Webb's case, he wished to state that he did not know whether a fish bone is more likely to perforate the intestine than anything else. During past years he had the experience of seeing several cases of swallowed foreign body. One child had swallowed ten pins, and they all passed through without any accident. Two other children had swallowed open safety pins. On the other hand, one would think that swallowing of fish bones is not so common. He had seen one case which had perforated the intestine and caused an abscess in the abdominal wall, where the fish bone was found at operation. He wondered if fish bones more frequently perforated the bowel than other sharp foreign bodies. And where there is a Meckel's diverticulum and a fish bone perforating that diverticulum, Dr. Johnson thought was a rare case.

Dr. R. C. Webb thanked the members for their discussion but was not surprised that there was no one in the society who had had a case of Meckel's diverticulum perforated by a fish bone even in this state which is so noted for its fishing.

Dr. Webb also referred to the method of drainage described by Dr. Bratrud and felt that it was noteworthy that the discussion did not show that Dr. Bratrud's enthusiasm was more general in the Society. Mikulicz, many years ago, drained many wounds by placing a gauze sack in the wound and stuffing it full of gauze. Gibson, about twenty years ago, modified Mikulicz's method by using a large piece of rubber-dam instead of the gauze sack. The rubber-dam makes the tampon much less painful and the folds about it and the holes in it afford satisfactory drainage. Dr. Webb presented a paper on this subject before this society nine years ago and he felt that Dr. Bratrud's use of a rubber glove was a very good substitute when operating in hospitals where the rubber-dam was not available. He felt that the surgeon who would try the use of this method of drainage would soon be brought to share Dr. Bratrud's enthusiasm.

Dr. William T. Peyton read his Inaugural Thesis entitled "Report of a Case of Tumor of the Thoracic Vertebra with Complete Paraplegia. Treatment with Radium with Complete Cure and Return of Function. Experimental Work Showing the Action of Radium on the Spinal Cord."

ABSTRACT

The cases here reported were cases of myeloma involving the thoracic vertebræ with compression of the spinal cord resulting in paraplegia.

The first case was treated by laminectomy and insertion of radium, this followed by high voltage X-ray therapy, with the result that the patient has been clinically free from symptoms up to the present time, eighteen and a half months after operation.

The second patient is one who had laminectomy only; this was followed by slight improvement. He is now receiving high voltage X-ray therapy. It is four months since the laminectomy was performed.

The results are reported of some experiments which were performed in an effort to determine the effect of radium upon the spinal cord of dogs. Photomicrographs of the cords of these animals removed after being exposed to different doses of radium are shown. Changes are produced in the meninges, and in the cord proper by this exposure to radium. The intensity of these reactions is directly proportional to the amount of radiation. The changes noted are a meningeal reaction over a localized area at the site of the implantation, characterized by infiltration of leukocytes. Changes in the cord proper are nerve cell injury and glial proliferation with smaller doses, but in larger doses there is nerve cell destruction, myelin degeneration, hemorrhages, and even fragmentation of the gray matter and focal necroses in the white matter. The maximum dose of radium placed extradurally which was tolerated without resulting paralysis was 1.7 millicuries.

DISCUSSION

Dr. S. H. Baxter said he was interested in Dr. Peyton's experimental work on the effects of radium on the tissue of the central nervous system. In considering these effects, it is necessary to bear in mind that radium, in its physical properties, is not a simple element and that its effects depend upon the manner in which it is applied. In the experimental work cited by Dr. Peyton, the radium was used in the form of emanation, in seeds, in which there is little filtration or protection against the alpha rays. This supposition is strengthened by the fact that, in the experiments cited, the destructive effect was in the immediate vicinity of the seeds. On the other hand in the operation which Dr. Peyton reported, the radium was applied in a metal needle so that although the dosage, measured in milligram hours, was a good deal greater than that which produced destructive effects when seeds were used, still there was apparently no harmful effect upon the cells of the spinal cord after exposure to the radium in the metal needle. Dr. Baxter said he had frequently exposed peripheral nerves to large amounts of radium heavily screened, without harmful effects upon the nerves, but he realized that the cells of the central nervous system were probably much more sensitive to radium than were the peripheral nerves. He asked Dr. Peyton whether he had any experimental evidence on the effects of radium, heavily screened and applied at some distance from the cord, upon the nerve cells.

Dr. Peyton (in closing) stated, in regard to filtration, that the alpha rays are filtered out in these seeds because it is 0.2 millimeters of gold. The nickel-steel is 0.5 millimeters, but gold is a better filter than nickel-steel. As far as the use of radium in the axilla is concerned, it is generally admitted that the peripheral nerves are very radio resistant. Dr. Peyton said that apparently very little actual work has been done on the effect of radium on the peripheral nerves.

As far as the cord getting more radiation from these needles which he had used in the clinical case, in comparison to the dogs which were experimented on, Dr. Peyton said it really got less because he had put these out at a distance; and the effect of radiation decreases so greatly with distance that when he figured this out in terms of skin erythema doses he found the clinical case actually got less.

The annual election of officers took place at a business meeting which was held immediately following the scientific program, and the following officers were elected for next year: President, Dr. Kenneth Bulkley; vice president, Dr. Martin Nordland; secretary-treasurer, Dr. F. A. Olson. Council members: Dr. R. C. Webb was elected in place of Dr. White, whose term expired; Dr. A. E. Regnier was elected to fill Dr. Nordland's unexpired term.

The meeting adjourned.

H. O. McPheeters, M.D., *Secretary.*

BOOK REVIEWS

BOOKS RECEIVED FOR REVIEW

Medical Formulary. E. Quin Thorton, M.D. Assistant Professor of Materia Medica of Jefferson Medical College. Philadelphia. 352 pages. Price, $2.50, flexible binding. Philadelphia: Lea & Febiger, 1932.

Psyllium Seed: The Latest Laxative. Dr. J. F. Montague. Medical Director Montague Hospital for Intestinal Ailments, etc. 170 pages. Illus. New York: Montague Hospital for Intestinal Ailments, 1932.

Modern General Anesthesia. James G. Poe, M.D. Lecturer on General Anesthesia in Medical and Dental Departments of Baylor University, etc. 231 pages. Illus. Price, $2.50 cloth. Philadelphia: F. A. Davis Company, 1932.

The Way of Health Insurance. A. M. Simons and Nathan Sinai. Research Staff of Committee on the Study of Dental Practice of the American Dental Association. 215 pages. Price, $2.00, cloth. Chicago: The University of Chicago Press, 1932.

Growth and Development of the Child. Part III. Nutrition. Report of the Committee on Growth and Development, Kenneth D. Blackfan, M.D., Chairman, White House Conference on Child Health Protection. 532 pages. Price, $4.00, cloth. New York: The Century Co., 1932.

Fertility and Sterility in Marriage. Th. H. Van de Velde, M.D., formerly Director of the Gynecological Clinic at Haarlem, Holland. Translated by F. W. Stella Browne. 494 pages. Illus. Price, $7.50. New York: Covici-Friede, 1932.

Nutrition Service In The Field. Child Health Centers: A Survey. White House Conference on Child Health Protection. 196 pages. Price, $2.00, cloth. New York: The Century Company, 1932.

Obstetric Education. White House Conference on Child Health Protection. 302 pages. Price, $3.00, cloth. New York: The Century Company, 1932.

THE HUMAN VOICE. Leon Felderman, M.D. First Edition. Cloth. Price $2.50. 294 Pages, with illustrations. New York: Henry Holt and Company, 1931.

This handy-size book, written in popular style, supplies topographical knowledge of the upper air passages and their common disorders. It is offered as an auxiliary to vocal instruction and has been compiled to bridge over the difficulties between vocal teacher and pupil: to bring them closer together on the common ground of knowledge. The anatomical descriptions are given in terms understandable to the layman, and the line drawings, excepting those pertaining to the nose, are good.

The author maintains that vocalization and its esthetic qualities cannot satisfactorily be taught to large groups. Each individual pupil must have his particular teacher.

In the chapter on swimming, he states that indoor or tank swimming is far less dangerous than outdoor swimming. He stresses the dangers of forcibly blowing the nose right after swimming. Those individuals with a history of discharging ears, perforation of the drum membrane, or sinus infection should be regarded as bad swimming risks unless examination by a competent otolaryngologist proves otherwise.

"The removal of the tonsils when diseased adds materially to the welfare of the patient and does not affect the voice."

The author denies the harmful effects of tobacco.

This book should be of value to anyone interested in the training of the voice.

The publisher is to be congratulated on the high quality of print and paper employed.

H. J. Rothschild, M.D.

JUDGMENT ON BIRTH CONTROL. R. de Guchteneere. Price $2.00. New York: The MacMillan Company, 1931.

This book, written by a Belgian physician, gives a broad view of the entire subject of birth control. It explains Malthusianism and gives the facts concerning that doctrine. Next it takes up Neo-Malthusianism and the various modifications of it which have led to the present widespread Birth Control movement. In the next four chapters the subject of birth control is discussed from the economic, eugenic, medical and moral aspects. Throughout these chapters the judgment against the Birth Control movement is based on scientific reason in support of natural law and demands the consideration of science and common sense without regard to religious teaching.

The remaining fifteen pages show the parallel between these conclusions and the Catholic view of birth, and stress the rôle of religion as opposed to paganistic individualism in bringing the human will into conformity with natural law in the interest of humanity.

Charlotte A. Stickney, M.D.

FOR SALE—To close estate: Completely equipped Minneapolis physician's office, including Fluoroscope, X-ray, Stereoscopic Viewer, Metabolor. Phone number and same space is desired. Cash or reasonable terms. Howard P. Quealy, Administrator, 754 McKnight Building, Minneapolis.

FOR SALE—Office equipment including X-ray. Location in Minnesota town of 1,400 people. Average income of over $5,000 yearly for the past eight years. Unopposed. Specializing. Address D-150, care Minnesota Medicine.

YOUNG LADY, twenty-seven, wants position as office girl serving group of doctors. Vast experience in meeting public. Best references. Address D-174, care Minnesota Medicine.

COMPETENT SECRETARY-STENOGRAPHER desires position in doctor's office, clinic, or hospital. Several years' experience, including secretary to medical editor. Call Dale 2619 (St. Paul), or address D-173, care Minnesota Medicine.

NURSE TECHNICIAN desires position in clinic, doctor's office or laboratory. Several years' nursing and office experience. Laboratory training. References. Address D-172, care Minnesota Medicine.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

THREE GENERATIONS of experience in grinding, specializing in fine surgical instruments. Prices, reasonable. Schwarz Grinding Service, Foot-Schulze Bldg., 128 10th St. E., St. Paul. Telephone, Midway 9939.

YOUNG LADY TECHNICIAN would like a position in Clinic, Hospital, or Doctor's Office. Experienced in X-ray, physiotherapy, and all clinical laboratory procedures. Outside of Twin Cities preferred. References. Address D-167, care Minnesota Medicine.

FOR SALE—Equipment of Granger Clinic—X-ray outfit, microscopes and laboratory equipment, sterilizers, cabinets, tables, etc., metabolism apparatus, gas machine, and other articles; also large library. Retiring from practice. Address Dr. Chas. T. Granger, Rochester, Minn.

LIST OF PHYSICIANS LICENSED BY THE MINNESOTA STATE BOARD OF MEDICAL EXAMINERS, MARCH 1, 1932

BY EXAMINATION

(January)

Name	School and Date of Graduation	Address
Albers, Edward Charles	U. of Pa., M.D., 1930	Mayo Clinic, Rochester, Minn.
Austin, Villairs Thomas	U. of Ore., M.D., 1929	Mayo Clinic, Rochester, Minn.
Andre, Hugo Carl	U. of Minn., M.B., 1931	3019 37th Ave. S., Minneapolis, Minn.
Baker, Abe Bert	U. of Minn., M.B., 1930; M.D., 1931	621 Oliver Ave. N., Minneapolis, Minn.
Beckman, Wallace Gerald	U. of Minn., M.B., 1931	Swedish Hospital, Minneapolis, Minn.
Biederman, Albert Alfred	U. of Minn., M.B., 1931	General Hospital, Minneapolis, Minn.
Blumstein, Alex	U. of Minn., M.B., 1930; M.D., 1931	335 St. Anthony Ave., St. Paul, Minn.
Cook, Norman Corrigan	U. of Man., Canada, M.D., 1930	Mayo Clinic, Rochester, Minn.
Danielson, Julia Hanson	Rush Med. Col., M.D., 1931	Litchfield, Minn.
Danielson, Lennox	Rush Med.Col., M.D., 1931	Litchfield, Minn.
Doroshow, George David	U. of Minn., M.B., 1931	1352 Goodrich Ave., St. Paul, Minn.
Faue, Clarence George	U. of Minn., M.B., 1931	1515 Charles St., St. Paul, Minn.
Freeman, Leonard, Jr.	U. of Colo., M.D., 1929	412 4th St. S. W., Rochester, Minn.
Garvin, Robert Odell	U. of Pittsburgh, M.D., 1929	Mayo Clinic, Rochester, Minn.
Ghiselin, Alex. Dickinson, Jr.	Columbia Univ., M.D., 1929	Mayo Clinic, Rochester, Minn.
Goodwin, Thomas Wright	U. of Georgia, M.D., 1930	Mayo Clinic, Rochester, Minn.
Hottinger, Raymond Creighton	Creighton Univ., M.D., 1930	Janesville, Minn.
Kettlewell, Ralph Burnsell	U. of Minn., M.B., 1931	2525 Garfield Ave. S., Minneapolis, Minn.
Keyes, Howard Craig	U. of Buffalo, M.D., 1928	Mayo Clinic, Rochester, Minn.
Kirch, Walter	Royal Univ. of Florence, Italy Diploma of Doctorate, 1925	Mayo Clinic, Rochester, Minn.
Kugler, Alex. A.	U. of Minn., M.B., 1931	General Hospital, Minneapolis, Minn.
Lansbury, John	Queen's Univ., Canada, M.D., 1926	Mayo Clinic, Rochester, Minn.
Martin, Melvin Sylvester	U. of Minn., M.B., 1930; M.D., 1931	Sedan, Minn.
McDonald, Angus Morris, Jr.	U. of Pa., M.D., 1928	Mayo Clinic, Rochester, Minn.
Mork, Byron O., Jr.	U. of Minn., M.B., 1930; M.D., 1931	Worthington, Minn.
Ouellette, Alfred Joseph	Loyola Univ., M.D., 1931	707 Fullerton Pkwy., Chicago, Ill.
Parkhill, Edith Muriel	U. of Wis., M.D., 1930	624 4th St. S. W., Rochester, Minn.
Parker, Wilbert Howard	U. of Wis., M.D., 1930	Eyota, Minn.
Purves, George Harland	U. of Minn., M.B., 1931	St. Mary's Hospital, Duluth, Minn.
Raaf, John Elbert	Stanford Univ., M.D., 1930	Mayo Clinic, Rochester, Minn.
Robertson, Murl John	U. of Minn., M.B., 1930; M.D., 1931	Bayfield, Wis.
Rogers, Sydney Francis	U. of Minn., M.B., 1931	906 E. 6th St., St. Paul, Minn.
Rosenthal, Nāna Lu	Col. of Med. Evang., M.D., 1931	800 W. Winona St., Austin, Minn.
Rosenthal, Frank Harold	Col. of Med. Evang., M.D., 1931	800 W. Winona St., Austin, Minn.
Rudolph, Edward August	U. of Mich., M.D., 1931	Mayo Clinic, Rochester, Minn.
Schamber, Dean	U. of Minn., M.B., 1931	513 Summit Ave., St. Paul, Minn.
Sisk, Harvey Ernest	U. of Minn., M.B., 1931	Mazeppa, Minn.
Stafford, Charles Eugene	U. of Minn., M.B., 1930; M.D., 1931	Kensington, Minn.
Thorp, Edward George	Harvard U., M.D., 1929	603 1st St. S. W., Rochester, Minn.
Van Hale, Laurence Aloys	U. of Minn., M.B., 1931	951 14th Ave. S. E., Minneapolis, Minn.
Van Slyke, Cassius James	U. of Minn., M.B., 1927; M.D., 1928	3925 Pillsbury Ave., Minneapolis, Minn.
Watz, Clarence Emanuel	U. of Minn., M.B., 1931	Ancker Hospital, St. Paul, Minn.
Wood, George Thomas, Jr.	Jefferson Med. Col., M.D., 1928	Mayo Clinic, Rochester, Minn.

MINNESOTA MEDICINE

Journal of the Minnesota State Medical Association, Southern Minnesota Medical Association, Northern Minnesota Medical Association, Minnesota Academy of Medicine and Minneapolis Surgical Society.

VOL. XV JUNE, 1932 No. 6

PUBLIC HEALTH ORGANIZATION AND THE MEDICAL PROFESSION*

A. J. McLaughlin, M.D.
Medical Director, United States Public Health Service, Interstate Sanitary District No. 3
Chicago

THE development of present day practice of public health and preventive medicine is a glorious achievement. The major credit for this must go to physicians both for the research results and for the application of the knowledge of disease prevention thus secured. There are, of course, notable exceptions. Pasteur was a chemist and many research workers who discovered facts in preventive medicine were not physicians, but almost without exception the men who have brought order out of chaos and who have developed health departments to their present state of efficiency have been physicians. Not only were doctors responsible for the major part of the discoveries, but it was the doctor acting as health officer who applied this new knowledge, and developed the system of wholesale preventive medicine which is the chief objective of health departments today.

All this development of preventive medicine was the work of doctors as individuals interested in the possibilities of preventive medicine. Collective action by medical societies for developing preventive medicine was conspicuously absent until the past decade. The overwhelming majority of practicing physicians up to recent times did not practice preventive medicine. This was not their fault. They had been taught to care for the sick and injured and preventive medicine was not taught in our medical schools to undergraduates in an effective manner until the present decade.

Since 1900 preventive medicine has made rapid progress in health departments due to the vigorous efforts of health officers. The great unofficial health agencies by educational propaganda have insisted on prevention and the development of facilities for prevention rather than cure.

During these past three decades the practicing physicians have held to what they considered their primary duty of treating the sick and injured. They have been reluctant to establish clinics for examination of apparently healthy people or to immunize or vaccinate against disease except upon individual request. It was natural, therefore, that both official and unofficial health agencies, in their enthusiasm, and in the absence of facilities for early diagnosis, should establish clinics and create in the public mind by education a demand for protection against contagious disease by immunization and for the discovery and early correction of disease and defects.

Unofficial agencies and the great foundations devoted large sums of money for preventive work, educational and otherwise, and official health departments secured large appropriations for the prevention of diphtheria, typhoid fever, tuberculosis and later venereal disease.

As a result, practicing physicians saw all kinds of clinics develop and expand which seemed to be taking their patients away from them. In the past forty years public health administration established both fixed and traveling clinics, conducted wholesale immunization campaigns and examinations for discovery of defects in school children. All of this is work that should be done by the practicing physician. The only excuse for the invasion of the physicians' field was that physicians, individually and collectively, would not practice preventive medicine. No health officer could sit idly by, while children died, incipient tuberculosis became advanced and venereal disease ran rampant—when aggressive action, though wrong in principle as an invasion of the physicians' field, could prevent this unnecessary loss of life.

---

*Presented before the Minnesota State Sanitary Conference, St. Paul, December 14, 1931.

The gulf thus developed between the practitioners of preventive medicine and the practitioners of curative medicine should never have been created. It is now fortunately being bridged over and eliminated. Preventive medicine is now being taught to undergraduates in all Class A medical schools. Medical societies as collective units are preaching preventive medicine. The average practicing physician now recognizes preventive medicine as his job, and the more progressive ones concede it to be the more important part of their job.

Even with the amazing development of preventive medicine activities since 1900, the immunization campaigns, drives for early discovery of diseases and defects, pre-natal clinics, baby welfare stations, clinics for tuberculosis, venereal and other diseases, certain fundamental defects are apparent in our public health programs which can only be corrected by the concerted effort of county medical societies properly organized, or by further expansion of state medicine into the doctors' field.

1. *Maternity and Infancy.*—Health departments and unofficial activities have secured results in reducing very greatly the infant mortality rate, but this reduction is almost entirely in children over one month old. The death rate for mothers and for babies under thirty days old still remains unnecessarily high. The only way in which this high rate for mothers and children under one month can be reduced is by better prenatal and obstetric care by physicians, who have had proper, adequate training in obstetrics and who have available expert consultant advice and lying-in hospital and clinic facilities. The ignorant midwife is responsible for much, but part of the blame attaches to physicians practicing obstetrics without adequate training or experience and who do not have access to expert advice or a lying-in clinic and hospital. To correct this is the job of the organized county medical society aided by the state medical society and the medical department of the University.

2. *The Pre-School Child.*—Our greatest defect in public health work today is our failure to secure preventive work in the child from one to five years old. With all our clinics, splendid work by public health nurses, efforts of parent-teachers and other organizations, we have barely scratched the surface in this field. Preventive medicine in this age group can only reach its full possibilities through the initiative of the properly organized county medical society assuring the individual participation of all its members. The health department with this coöperation could thus secure the necessary preventive work in this age group, instead of waiting for school age.

3. *Preventive Medicine for the Adolescent and Adult.*—Here the great need is general practitioners who have knowledge of modern technic for early diagnosis in the incipient stage and who have such equipment available. It is too much to expect that they should have this equipment in their individual offices; but the equipment and apparatus should be readily available, within easy reach and freely used. Too often we find plain symptoms of gastric or duodenal ulcer treated for months by prescription as indigestion; incipient tuberculosis treated by prescription for months without diagnosis until it becomes moderately or far advanced; pathologic conditions of gallbladder or appendix without a Graham test or X-ray treated for months by prescription until some acute climax forces operation or causes sudden death; hyperthyroidism and hypothyroidism receiving perfunctory office treatment by prescription without basal metabolism tests; treatment of female genital complaints by tampons or by guesswork surgery; and office treatment of many other conditions without the use of modern diagnostic methods.

In the large cities and medical centers the diagnostic equipment is available and more likely to be used, and the general practitioner of fifty or more years of age is likely to have kept pace with the advances in diagnostic technic. In the small cities and towns and in the large rural areas, where the average age of physicians is fifty-two years, it is quite another story. If a man or woman not acutely ill asks for examination or treatment, the examination is perfunctory and incomplete. The campaign and propaganda for annual physical examinations of the apparently healthy fell far short of its possibilities, because in cities the examination costs too much or the applicant fears an unknown cost, while in the small cities and towns and rural areas the facilities for complete examination did not exist.

FACTORS IN THE FAILURE OF ORGANIZED MEDICINE TO CORRECT THESE DEFECTS

1. *Lack of Organization.*—We speak of the organized medical profession, but its organization is little more than provision for periodic meetings for the reading and discussion of papers on scientific subjects. An exaggerated sense of ethics makes many physicians shrink from anything like business organization; yet organization on a business basis, provision of clinic facilities, regulation of fees on a sliding-scale basis according to income are essential if State medicine is to be prevented. There are notable exceptions. The medical society of Kings County (Brooklyn), the New York Academy of Medicine, and the Wayne County (Detroit) medical society have taken steps toward business organization with a view toward social service, but, except for these and a few others in the large cities, county medical societies are unorganized except for periodic scientific meetings. The business side of their real obligation, to establish facilities for the best preventive medicine and surgical advice and treatment at a price that each citizen can afford, is entirely neglected.

2. *Cost of Medical Care.*—The best modern medical care is worth all you pay for it, provided you can afford the cost. The cost has not increased out of proportion to the costs of other services. Medical care, especially early diagnostic procedures and treatment, has been expanded and amplified by the discovery of more precise methods of diagnosis and has become exceedingly complex. This necessarily increases the cost of examination as compared with that of forty years ago, when the physician used only his own senses and perhaps a stethoscope.

In the large cities the facilities for early diagnosis and for the best preventive medical and surgical care are available. The trouble here is that the man of moderate means does not know what it will cost; and, fearing that the cost will be excessive, he avoids the doctor and the clinic and neglects himself and his family until serious illness or injury results. In the small cities, towns, and rural areas, lack of proper early preventive treatment is not due to the cost, but is due to lack of facilities for early diagnosis and treatment. I have seen in many small cities a small modern hospital approved by the American College of Surgeons but without an out-patient department. What does this mean? There is no provision for preventive medicine; a man must be knocked down by an automobile, have typhoid fever or pneumonia, in other words, be seriously injured or acutely ill before he comes in contact with the modern equipment of such a hospital. There must be a decentralization of modern equipment from the large cities and medical centers to the small cities and towns, and also a better distribution of young physicians who know how to use this equipment.

3. *Distribution of Doctors.*—Next to the need for out-patient facilities and modernly equipped clinics, the greatest need in the small city, town and rural areas is for more and better trained physicians.

The young medical graduate of a Class A school today is trained in preventive medicine and is taught to use the modern instruments of precision in diagnosis. He learns to depend upon the modern facilities which are used in his college and hospital training. These are available in the city, and, hence, he stays in the large city. He will not go to the small town because these facilities do not exist and he cannot practice medicine in the way he has been taught. Here again the remedy is obvious—there must be decentralization of modern diagnostic and treatment facilities from the large cities and medical centers to the small city.

In the distribution of young, highly trained graduates, the law of supply and demand is inoperative. Why? The reasons given above explain. The young physician would go to the small city or town where the demand for his services is greater, and the remuneration also greater, rather than practice in the keen competition of the city over-crowded with physicians, provided he could practice medicine in the modern way with modern facilities, which he considers indispensable.

REMEDIES SUGGESTED FOR CORRECTION OF THESE DEFECTS

1. *Provision by County Medical Societies for Equipment for Early Diagnosis and Treatment.*—The citizens living in small cities, in towns, or rural areas are, in common justice, entitled to the use of up-to-date facilities for diagnosis and treatment quite as much as the wealthy or the poor living in the large city or medical center.

The county medical society should establish or cause to be established in the county seat and, in populous counties, in other small cities outpatient clinics completely equipped for early diagnosis and treatment. They should fix the fees on a sliding scale according to income—for example, dividing the clientele into three or more classes, as follows:

a. The indigent to be paid for by the county at a fixed rate.

b. Those earning less than $1,500 per annum to pay a minimum fee.

c. Those earning from $1,600 to $2,400 per annum to pay a higher fee.

d. Those earning over $2,400 per annum to pay full fees.

The fees for house or office visits should be determined for those same classes. The facilities for diagnosis or treatment in the out-patient clinic or hospital should be available to all members of the medical society and the fees collected divided pro rata.

2. *State Medicine.*—The term "state medicine" is used here because it commonly signifies the bogey that continually confronts the practicing physician. State medicine means the assumption by the Government (Federal, State, or municipal) of the obligation to give every citizen or group of citizens medical and surgical care. In general, this would mean the State government; but the same results, as far as the practicing physician is concerned, are possible by the encroachments of private corporations which assume this obligation for their employees, using salaried physicians to do the work.

The advocates of State medicine have claimed that the defects noted above in our public-health activity would be corrected by State medicine, because medical and surgical and, presumably, preventive advice and treatment would be available to all citizens without cost. One must admit that, theoretically, under such a system, treatment would be available to all; but some doubt that there would be entire satisfaction with the quality of such medical care. The average American citizen feels that he is entitled to adequate treatment, and he has been educated to the point where he knows something of the newer methods and equipment used in modern diagnosis and treatment.

In presenting this paper there were two objects in mind: the first concerning the practicing physician; the second concerning pubic health administration. I should like to see the medical profession solve its own problem in its own way without outside interference by governmental or any other agency. Proper organization of county medical societies will make State medicine impossible, enable the physician to retain his self-respect, and preserve that priceless, intimate, confidential relation that should exist between physician and patient. In regard to the second objective, more efficient public health administration, this same organization of county medical societies would also correct the defects in our public health activity cited above. It will make possible better lying-in facilities and better consultant advice for prenatal work. It will provide the machinery now lacking for early diagnosis and treatment of diseases or defects in the pre-school child and in adolescents and adults as well.

THE INEVITABLE END OF PUBLIC HEALTH WORK

W. G. Richards, M.D.
Billings, Montana

In reviewing the history of public health work one notices a constant widening of the conception as to what constitutes its legitimate scope and a continued broadening of its field of activity. At first simply an agency for the prevention of the spread of contagious disease, its attention was confined to quarantine regulations and a so-called terminal disinfection, the efficiency of which seemed to have been gauged more by its offense to the olfactory organs than by any real knowledge as to its lethal effects on the bacteria concerned. Elementary common sense, however, soon suggested that the best way to control such diseases was to prevent their originating, and knowledge was sought of the causes and means of destroying these before they could produce disease. Thus the connection between typhoid fever and the water supply was discovered, and public health work had to extend itself into the field of sanitary engineering.

Similarly blind quarantine and fumigation had little effect on the incidence of yellow fever, but when its connection with the mosquito was learned it became possible to wipe the disease out, though to do it the health department had to take upon itself the task of draining swamps.

Contagious disease, however, constitutes but a relatively small part of the ill health of a community, not more than 5.6 per cent, according to De Porte[1] after making a survey in New York state. Progressive health officers have, therefore, not hesitated to extend their operations in any direction in which they think they see an opportunity to lessen morbidity. Thus, when the connection between endemic goiter and lack of iodine was demonstrated, they exerted themselves towards seeing that growing children were supplied with a sufficiency of that element, and have also promoted soil surveys to determine its iodine content. The possibilities from an extension of this work are great, for we really know very little of the mineral metabolism of the body, and insufficiency of inorganic constituents of foodstuffs may have much to do with disease.

It has been difficult, however, to bring the public to an appreciation of positive health measures. It is always easy to get them to visualize the dangers of a person sick with a disease like smallpox, and measures directed towards a curtailment of such an individual's activities are fairly sure of receiving general approval, though possibly not of the individual himself, but methods of disease prevention which require some definite action on the part of those apparently well are not so well received, as witness vaccination against smallpox. Difficult also has it been to bring people to a realization of the fact that apparent health may not be real health, that disease may be latent or masked, only to be appreciated by the expert, or that, while a person may not be actually diseased, his bodily processes may be working poorly on account of faulty habits or a bad environment, or that the development of children may be impaired because of the ignorance or poverty of the parents or guardians.

Neither has it been easy to obtain public acceptance of the idea that these were matters which concerned any others than those immediately affected. Each individual was supposed to be able to work out his own salvation, and how he and his family lived was nobody's business but his own. Even the churches, which had theoretically long answered in the affirmative Cain's question, "Am I my brother's keeper?" seemed to fail to see the logical implications of their answer, and though often waxing eloquent over the pitiable plight of the poor benighted heathen, whose uniform, as Kipling expressed it, "wasn't much before, and rather less than half of that behind," frequently failed to visualize the still more pitiable condition of the child at their doors, who had to meet the rigors of a northern winter with insufficient calories inside him, and too little clothing outside him to keep even these few calories in.

Some there were, however, who took their religion seriously, and, aided by pure humanitarians, and not a little, be it said, by so-called radical politicians, succeeded in educating public opinion on these matters until legislative and other measures were initiated to mitigate in some degree the evils. Further, business and commercial leaders began to appreciate that sickness and malnutrition in their workers represented an economic loss to them, while the World War focussed attention on the large number of men whose efficiency as war material was impaired or altogether destroyed by physical deficiencies which could have been prevented. Thus a combination of altruistic and purely utilitarian motives succeeded in bringing about a very much greater interest in public health work until now we have almost an embarrassment of riches in agencies to promote it, often, I am afraid, to the discomfiture of the health official, who has to serve as a buffer between the proponents of the various plans and the legislature from which he has to extract the necessary financial assistance.

Unfortunately, these activities largely lack intelligent direction and coördination. Depending, as many of them do, on private initiative, they are necessarily often erratic and sporadic. One community may be the possessor of an energetic and public spirited citizen who by sheer force of personality focusses attention on these matters and gets things done, while an adjoining community, lacking such a guiding spirit, is altogether neglectful of them. Boards of health, especially local ones, are in similar plight. The progressive community has an efficient full-time health service, while the unprogressive one satisfies itself with the casual ministrations of some more or less competent doctor, who expects to make up for the deficiencies in remuneration by the advertising which he thereby obtains. The very fact, however, that such a gesture of public health service is made at all is eloquent testimony to the success of the campaign of education which has been carried on. In one phase of it, the care of infants and children, so far have we gone from the old doctrine of the parent's exclusive rights and responsibilities, that President Hoover, whom no one could accuse of socialistic tendencies, can say:[2]

"The ideal to which we should strive is that there shall be no child in America that has not been born under proper conditions, that does not live in hygienic surroundings, that ever suffers from under-nourishment, that does not have prompt and efficient medical attention and inspection, that does not receive primary instruction in the elements of hygiene and good health, that has not the complete birthright of a sound mind and a sound body, that has not the encouragement to express in fullest measure the spirit within which is the final endowment of every human being."

All of which is very good, and may be presumed, I suppose, to express the attitude of the major political party in this country, in other words, the consensus of American opinion, but we have a long way to go before achieving these ideals, and our politicians will have to enlarge many of their conceptions as to the functions of government before we do so.

If the child is to live in hygienic surroundings attention will have to be given to the problem of housing. I do not believe that any country in the world can show a larger proportion of fine homes, well equipped with facilities for good living, than America. But can anyone familiar with the living conditions of the poor in both town and country—and remember that here, as elsewhere, the poor, the relatively poor, if you will, make up the mass of the population—maintain that these are satisfactorily housed? Slums in the city and shacks in the country abound, and, though to have been born in a log cabin may be an asset if one aspires to be president, continued living under such conditions does not make for health. Hilda Rose's Stump Farm is a revealing illustration of life on a homestead, and no one with personal knowledge of these conditions can say it is overdrawn.

To be born under proper conditions means that every pregnant woman has medical care and supervision; that, if unable to provide it for herself, she is furnished proper food, and that her confinement takes place either in a hospital or some house where the necessary facilities can be obtained. Those of us who have done obstetrical work, either in the town or country, know how widely the actual conditions fail of the ideal. I have myself delivered women in places which I would not have chosen for the parturition of a valuable dog. Many women receive no attention at all until their hour arrives, and then hasten to secure the services of any doctor they can manage to get hold of. That they get one at all is often a matter of luck, for, knowing how poor are the chances of getting paid in such cases, doctors are becoming increasingly shy of attending them, and I think there is a growing feeling of resentment in the profession at having the burdens which should be assumed by society in general thrust upon their unrequited shoulders. Antenatal clinics have been organized in some places to meet some of these needs, and do good work, but, as emphasized at the Congress of Obstetricians and Gynecologists at Dublin,[3] the only suitable individual to take care of a woman during her pregnancy is the one who is to attend her during her parturition.

How much "prompt and efficient medical attention and inspection" does the average infant get? Unless some gross nutritional condition or an infectious disease arises it is never seen by a doctor at all. The milder degrees of malnutrition, the chronic diseases, are all generally overlooked, perhaps to be discovered when it is too late to do anything for them. Some of our women's organizations are making praiseworthy efforts to provide for their needs by holding occasional clinics, to which mothers are invited to bring their children for inspection, but though undoubtedly much good is done in this way, it is at the best a makeshift arrangement. It does not provide the constant attention which alone can secure proper results; neither is there any assurance that the medical attention is of the efficient kind desired by the President, for generally it is expected to be given gratuitously, or nearly so, and such service is notoriously not always competent.

Perhaps the school child receives the most attention at present. But even here there is great diversity in method. Some schools have school physicians, more have school nurses, but many have no care at all. The provision of school nurses is altogether admirable, but adequate health service needs medical men and women. Notwithstanding the overloaded curriculum in training schools for nurses, and notwithstanding the ambitious examination questions to which nurses are subjected by state boards, many of which, by the way, I am perfectly sure I would fail on myself, nurses are not doctors. To make health examinations needs expert diagnosticians, even more so than to pick out the palpably sick. This can only be done by competent physicians, and these will often need specialist assistance, not forgetting the psychiatrist, for mental health is of no less importance than bodily health. Then, again, it is of no use to pick out the sick unless the necessary treatment can be provided for, and for this we need the family practitioner.

However, childhood is only a period of preparation. The child is an economic liability, and unless, when his period of training is over, he becomes and remains a useful producing member of the social organization which has borne the expense of training him, its money has been wasted. Like any other machine, in spite of the most meticulous care in its manufacture, as soon as it is put into active operation it becomes subject to the effects of wear and tear and accidents which impair its usefulness and necessitate constant care and attention. Therefore, as an economic and engineering proposition alone (and President Hoover is too good an engineer not to see it if it were brought to his attention), the acceptance of the principles laid down by him necessarily and unavoidably leads to the acceptance of the further principle that to the adult also must be secured good hygienic surroundings, proper food, and efficient medical supervision and care. There is no altruism involved in this. It is simply good business to see that money expended brings an adequate return.

Big business is already beginning to grasp this, more and more recognizing that the health of the workers is of as much importance as the condition of the machines they operate. Absence on account of sickness always produces more or less disorganization, the degree increasing with the importance of the individual involved. Accordingly many corporations now arrange for the medical examination and care of their employes as a detail of their business, and each individual, being part of the machine, is selected so that he will give as little trouble as possible. But their whole idea is to reduce costs, even their medical services being arranged on this basis. Dr. Watson, of the American Telegraph and Telephone Company, throws an illuminating sidelight on what can be expected from them in public health work when he says:[4] "Throughout industry in general the funds available for the employment of physicians will not permit medical departments to hire experts. Further, as medical work grows in any given industry, the various steps of examination will have allotted to them a time limit, indicating to the medical employe that he must likewise produce and get his product out with a certain amount of celerity." I suppose the next step in this process of speeding-up will be to put the patient on a conveyor, and have the various physicians do their part of the examination as he comes by.

But even if this service were of the best it still leaves out a large part of the community. There are those employed by the smaller aggregations unable to afford a medical department, those temporarily out of employment, the aged, and those who through sickness or other reasons have been "scrapped" by industrial concerns. These must depend upon what arrangements they can make personally for medical service, and, as they are the least able to pay for these services, they will either have to depend on charity or the benevolence of the private practitioner. This is a serious matter for him, for, as was emphasized to me recently by a general practitioner in Philadelphia, more and more are those best able to pay for service being taken from him.

For the efficient promotion of the nation's health we need some coördinated system which will make provision for the medical care of all the people at all times of their lives. This, I take it, is the logical end of all the public health teaching of the last few years. Both officially, as public health officers, and privately, as practitioners of medicine, the medical profession has been engaged in educating the public as to what could be done in the matter of improving or preserving their health. We have taught them how many diseases can be prevented. We have shown them the importance of proper food. We have stressed the value of periodic examinations. And so seriously has the public taken our teaching that they are now crying out for all these things. Unfortunately, however, it does not seem that at any time we have given serious consideration to the problem as to how these things are to be supplied. The economic side has been almost entirely neglected. At the same time that we have been emphasizing the need for medical services the cost of them has been rising, largely because of the improved methods we have adopted. X-ray examinations, blood chemistry, basal metabolism, electrocardiography, to mention only a few, are no longer luxuries but necessities, and the public have learned the value of them. As a result, they are exhibiting a most disturbing interest in the whole matter of medical practice as at present conducted. The magazines are full of articles on the subject, all showing a most pronounced dissatisfaction with the present conditions, and demanding that a serious effort be made to devise some more satisfactory method.

Typical of these is an article in the New Republic of June 5, 1929, "Public welfare workers have found that the cost of illness . . . has become so great as to involve the financial ruin of many families so afflicted, or, indeed, so prohibitive as to render proper medical care impossible. They have also found that the average professional earnings of physicians and surgeons are too low to offer a proper return for the elaborate education and training necessary to attain and maintain that high professional efficiency which is demanded at the present time." It goes on to say that "even in the cities a large proportion of the population goes without adequate medical attention. In the Mulberry district of New York it was found that 16 per cent of the persons confined to their homes on account of illness and 22 per cent of those too ill to be at work obtained no medical care from a physician." It concludes: "The subject is of such importance that a comprehensive canvass of the situation is imperative, and is a work of such magnitude that it must of necessity be governmental in character."

The recent action of the Chicago Medical Society has further focussed attention on the matter, and unfortunately left the impression that the medical profession is averse to any change. Personally I cannot help feeling that this impression has some slight basis. It is reflected in the attitude[5] assumed by the Journal of the American Medical Association towards the Sheppard-Towner bill, an attitude based, as far as I can gather, on its injection of federal activities into state affairs. One would be inclined to think that the writer was a dyed-in-the-wool Democrat from his enthusiasm for state rights. I do not notice the same righteous indignation against federal aid for good roads. It is too well known that without federal aid our automobiles would still be stuck in the mud most of the time. Personally, though I strongly believe in the academic doctrine of states' rights in general, I am sufficiently pragmatic to take advantage of federal assistance whenever it will do any good. I strongly suspect the editorial writer to be guilty of what the psychologists call rationalizing, the real reason for his attitude being the bogey of interference with private practice, a suspicion strengthened by the statement[6] that neither the Sheppard-Towner act nor the later bill "lays down any line of demarcation between the welfare and hygiene of mothers and children and the welfare and hygiene of the rest of the people," a neglect, to my mind, caused by the very simple fact that there *is* no line of demarcation, for whatever affects the welfare and hygiene of the mass of the people necessarily and consequently affects the welfare and hygiene of mothers and children. How indeed can the health of the mother and children fail to be affected by the sickness and consequent loss of earning ability of the husband and father?

In fact the attempt to draw a hard and fast line between what is known as public health work and general medical practice is an impossible one. They overlap in all directions, and because of this overlapping the efficient health officer is continually getting into trouble with the rest of his professional brethren for poaching on their preserves. It cannot be too strongly insisted on that no one has any vested rights in the sick. These are a national liability, and the nation, through its agencies, has the right—nay, it has a duty—to make whatever arrangements it deems best for their care. As public spirited citizens we should further these efforts, though as men of business whose services in the matter are required, we have a right to insist that fair and equitable terms be made for these services. We should see to it that we are not exploited, as we so often are under present conditions.

Fair and equitable terms, however, does not mean a system by which some men may amass fortunes. I can easily understand the satisfaction with the present system on the part of some of our medical hierarchy, especially those directing large and wealthy clinics. It must be very gratifying, and tickle one's self-esteem hugely, to be able to point to the large amount of charitable work done for the poor, the while one recoups oneself by charging outrageous fees to the well-to-do. Such medical largesse reminds me of the noble highwayman whose exploits used to thrill me as a boy, who held up the stage coaches and robbed the wealthy, and then from his unhallowed makings gave doles to the poor. In proportion to his income the average country doctor does more charitable work than the whole lot of them put together, and as a consequence he is dying out. This cannot be permitted, for we need him. No public health service can be effective which fails to include the man who visits the sick in their homes, and a coördinated system of medical service will provide for just remuneration to him and all engaged in practice. We can do without the medical plutocrats.

This coördinated system of medical practice, which will knit together boards of health and medical practitioners, having as its principal object the prevention of disease, but providing medical service for all the people who need it whenever they need it, and effectively carrying out President Hoover's expressed ideals, I believe can only be achieved by some system of insurance against sickness, such as is in practice in some of the European countries. What the details should be I do not pretend to know. Probably we should have to modify them to suit conditions here, though I do not believe we should find the fundamental conditions very different. Undoubtedly this country is rich, richer probably than any country ever has been, but here, as elsewhere and at all times, the riches are unevenly distributed. I read the other day that 90 per cent of the wealth of America is owned by 10 per cent of the population. Most people only just manage to make a living and meet their ordinary expenses, and when serious sickness comes large numbers are dependent upon public or private charity, often, indeed, the unaided charity of the doctor. There is no reason for believing that this will ever be different, for men and women are fundamentally unequally endowed with capacities, political buncombe to the contrary notwithstanding. The parable of the talents is as true today as when it was uttered. Some have ten, some five, some one, and some will even fail to use what little they have. One remembers in this connection the results of the army intelligence tests. Hewers of wood and drawers of water must many of these be all the days of their lives. If you believe that these inefficient ones should be ruthlessly left to the play of natural forces that they may be wiped out, then, of course, I have no argument, but in that case public health work has no meaning.

Any such system will have to be compulsory, at least for the masses, for otherwise those who need it most will not have it. Life insurance demonstrates this, for in spite of an army of solicitors many have none at all. By such a system the burden of sickness would be spread over the whole nation, like national defense, and when one considers the enormous amount at present spent under our uncoördinated system, I doubt if the total cost will be greater than it is now, even when all are properly provided for. Incidentally it is of interest to note that it has been estimated[7] that an average of $6.30 per capita per annum is spent in this country for drugs alone, as against 59 cents for public health work in 1923. You will have to have far more faith in drugs than I if you believe this money to be well spent. Whether this system of medical service should be run by government agencies as part of the public health service, or through the medium of private companies, is a matter to be carefully considered, but the more the element of private profit could be kept out the better. One calls to mind in this connection the methods of the Life Extension Institute. It would be reasonable to expect a contribution from the federal government, for every man (and under present conditions every woman) is expected to be at its call in time of war, and it is to its interest to see that its potential war material is kept in a condition to be fit for service when needed. For the same reason industry could be expected to contribute. I make no pretense to enumerate the details. The purpose of this paper is simply to plead for a consideration of the subject, to point out that the logical end of public health work demands such a system, and that, as in the past it has had continually to enlarge its conception of its legitimate field to achieve its purposes, so now it should take up the study of sociology for the same end.

If preventive medicine is to be developed, the gap between public health work and the general practice of medicine will have to be bridged, and though this to some of us may mean the giving up of some of our so-called independence, it will be but in accordance with the general spirit of the times, which has been so well expressed by Professor Shotwell in his book, War as an Instrument of National Policy: "A new attitude is revealing itself in business and internal economics, one which seeks to substitute for ruthless competition some measure of coöperation, so that each member of the community may have a larger share in increasing the common good."

PERIODIC HEALTH EXAMINATION: A DISCUSSION*

Monte C. Piper, M.D.
Rochester, Minnesota

THE first function of physicians is treating the sick. The process of a health examination is a definite departure from our usual vocation. It perhaps requires greater insight into human nature than is required in helping the ill back to health. There should be a nice balance of judgment between over-zealousness to correct what might be termed a normal abnormality and care to give attention to an apparently insignificant finding for which medical advice ought to be given. The doctor who probably best renders this service is the personal physician who knows something of the client's habits, his family, and his finances, and it can best be rendered in his own office.

The program of periodic health examination consists of an effort on the part of physicians to utilize preventive medicine which shall be all-inclusive to the laity. Its scope and possibilities are probably as great as any public health activity at present adopted. Child welfare and similar movements have made the public mind receptive. The present agitation for periodic examinations might be termed a "revival," for sporadic attempts have flared up and cooled off during the past eight or ten years.

Probably the most concerted effort is that of the health examination campaign of The Greater New York Committee on Health Examination. Its success promises profoundly to affect for the better the relations of the patient and the physician. The Greater New York Committee last April inaugurated a carefully formulated five-year program. They issue gratis to physicians a monthly pamphlet called the "Health Examiner." The movement is spreading over the country, and the aggressive medical profession of Minnesota will not be lagging.

The idea of examining well persons perhaps has a religious origin in an attempt to cleanse the soul. It was first recorded by Dr. Dobell in England in 1861 and again sponsored by Dr. George M. Gould of Philadelphia in 1900. In 1923 a committee of the American Medical Association, headed by Dr. Haven Emmerson, issued a pamphlet as a guide for examiners. This is well composed. The Canadian Medical Association issued a similar guide about 1928.

Preventive medicine recognizes the fact that early detection and correction of anatomic defects, faulty function, and unhygienic habits of life make for longevity and life-long physical and mental efficiency.

The scope of the examination is as broad as the ability of the examiner, its length may be gauged by the time available and the difficulties encountered, whereas its depth is measured in the benefits received by the one examined. The client has the assurance of well-being, and confidence that he has had a thorough analysis and any fault brought to his attention. The success of the movement depends on the physician. Social reforms are likely to be distrusted by the average mind; however, probably all men and women will welcome the word of their physician that after a careful examination he can find no unnaturally destructive process. The degree of expertness of the physician in the art of medicine will be reflected in whether his results have been worth while to his health clients. Tact will be required not to make a neurotic of a patient with an inconsequential heart murmur, and not to agitate an already introspective mind. Many adults accept abnormalities of body or function as predetermined and beyond their control and submit to them without thought of prevention, and often rightly so. Advice rendered should be such as will recall to the client the fundamental principles of hygiene that he learned in his youth and to make him healthfully conscious of his food, his activities, and his personal care.

---

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the annual Conference of Secretaries of the Component Societies of the Minnesota State Medical Association, St. Paul, January 23, 1932.

Such advice as you choose to give must be for the future well-being of the applicant. Variations from the usual, in the form of moderate hypertension, overweight, underweight, or overly active or overly passive physique or mentality may be entirely normal for the person examined. We have no definite proof to the contrary. Nor do we know that some of the bad habits of the world shorten life, nor that other good habits prolong it. Dr. Raymond Pearl, director of the Institute of Biological Research of Johns Hopkins University, through a clipping bureau, investigated all reports in the press of persons celebrated for having attained a ripe old age. He concluded from the large number of answers to questionnaires that a family history of longevity was the most common and potent factor. In fact, there is abundant proof that much harm has resulted from over-zealous faddists who are more positive in their prognostications than you and I know they have any right to be.

It is easy to look at a patient, and after a short discussion say, "Oh, you're all right," or "Perhaps I might listen to your heart and examine your urine; you should watch your weight a little," but such a procedure is not the purpose of this program. The examination should be inclusive, systematic, and comprehensive.

For complete physical examination, the applicant should be undressed, and he should be examined conscientiously. Here, I believe, the procedure should end unless you have found something really wrong. Help the client to feel that a negative result is the most satisfactory issue. No one ever died of flat feet.

Furthermore, such examinations should be more or less standardized so that Mr. Doe undergoes practically the same routine as Mr. Dee, who may be examined in another city. The examinations must be reasonable in length and cost.

All this calls for a form, and I wish to submit that form adopted by the Pennsylvania State Medical Association as fulfilling the requirements better than any I have so far seen.

There are four pages. The fourth is blank for additional notes and records.

No one can be absolutely certain of the significance of indefinite and minor symptoms. Nature compensates for more or less severe loss of tissue or function, and with or without extensive laboratory and specialized examinations one cannot always be sure of a client's condition. When elaborations of means of diagnosis are indicated, the health client becomes a patient.

Examples of the degree of compensation by nature are found in the heart, circulatory system, kidneys, lungs, and digestive tract; even in cases of cancer of the stomach, muscular weakness, instability of the nervous system, and so forth, such compensation is found. A person does not consider himself ill until he suffers from "dis-ease."

Physicians who almost exclusively have been in attendance on persons with disease, treating serious or long-established processes that have interfered with the patient's comfort or earning capacity, may not find themselves at once prepared to guide applicants for health services in the practice of personal hygiene. Yet the examiner accepts this responsibility. He must give opinions which will make his services worth while.

The previously outlined, completed examination is but a guide on which to indicate abnormalities, but this record does not tell as much of the client as does your personal impression. This is where the art of medicine is manifested.

Your final conference is the lasting contact, and the final five minutes fixes the ultimate value.

Your advice and prescription may be a few words of assurance, or it may be a dissertation on the proper functions of any part of the body, or advice as to overweight or underweight, digestive disorders, insomnia, nervousness, or sexual relations. If you have fulfilled your duties, the health applicant usually will be satisfied.

The importance of properly conducted health examinations has been felt to be so urgent that it is being incorporated in the curriculum of some of the leading medical colleges. Health magazines, radio talks, and newspaper articles are advocating its adoption. Organized medicine is reviving the interests of the profession. Some will find its exactness laborious and tedious. There should be definite systems of record and follow-up. Later, as the accumulating records pile up, tabulation of your findings and comparison of these with those of other communities will add interest. Valuable information of vocational age groups would undoubtedly be revealed. The only other similar record is that of army officers; it is found that in this selected class of healthy young men, degenerative changes become apparent after about five years. Records should be made adaptable to the punch card system for future tabulation. Some practitioners undoubtedly will seek additional training and guidance. In this respect the university extension courses might prove helpful.

As a résumé, I would say that the examination should consist of a carefully conducted physical evaluation of each applicant, recorded on a standard form adaptable to tabulation from all sections of the state. It should end there.

One of the most difficult functions of a physician is to keep well persons from believing they are ill, and this consultation should be so conducted as to state the client's real condition.

Above all things, no physician should approach this program with an idea of feeding patients to his practice.

ECONOMIC THERAPEUTICS*

Albert H. Parks, M.A., M.D.
Minneapolis

I AM offering no apologies for presenting this subject rather than a scientific one, because, if I am able to judge from the morning conversation about the staff rooms at our hospitals, this subject is a live one.

As some of you know and as Amos and Andy express it, "we are in a state of repression." This is seriously affecting the members of our profession, as it is all others and involved with us are our hospitals and our graduate nurses.

If this were the only consideration, I would say that time alone would effect a cure. However, the cause of our present troubles goes back much further than our present economic state. I believe it behooves us as a profession, and our allies, the hospitals and nurses, to take some thought as to the reasons for our present situation and if there be any way to the solution of some of our problems, and an answer to our lowered standing with the general public, that we put our minds and our concentrated efforts to the solution of that problem.

Military experts contend that the best defense is a strong offense. This rule may apply to us. Let us not deceive ourselves. The medical profession and in part our allies, the hospitals and graduate nurses, are not popular with the general public. In other words they don't like the way we do business. Some time ago I read a list of the popular magazines and periodicals that have, in the last year alone, published articles criticising our profession, mainly from the economic standpoint and partly from the viewpoint of the layman, in regard to our so called Ethics. This list was staggering. Something is wrong when such a barrage of criticism is fired at any group of men as is being directed at our profession. It is not sufficient to say, "We know we are all right and all the rest of you are wrong." Perhaps we are and perhaps not. At any rate, in this instance, virtue is not its own reward. It appears to me that it is time that organized medicine had a rather thorough soul examination to see if there may be anything to the contention of our critics.

---

*Read at the Asbury Hospital Staff, January 6, 1932, and re-read, by request, before the Hennepin County Medical Society, February 10, 1932.

Economic existence of our private hospitals is necessary to us as a profession, if we are to practise medicine. They are our workshops. It is necessary that we have competent trained nurses, as they are our allies. It is certainly necessary for the members of our profession, if we are to maintain the high standards set before us by our predecessors and to continue to advance in the science of practise of medicine as the times demand.

If we do not present a satisfactory answer to our critics and adjust ourselves to the demand of public service, the public, who is least competent to solve this problem, will answer it for us and probably unwisely.

I do not wish to pretend that I alone can suggest a corrective program but I do wish to present the following thoughts, which appear to me to be both critical and constructive, as the basis for argument and for your consideration and criticism, within our profession and not for public edification.

Publicity.—We have through our medical organizations and through years of undue emphasis on ethics, deliberately and with intent, kept out of the press, which is the general information source of the public, all except the most formal notices bearing upon the life work and activities of our profession and of our hospitals. Much of the material that has been presented and used by the press in a big way, has been public criticism of our profession by members or agents of our profession. As illustration, the widespread lectures and front page publicity a few years ago, that the majority of operations done in our hospitals were unnecessary ones and that anyone having lost a member of their family through operation or complications that must have developed in operative procedure, should promptly bear this fact in mind. This was front page news in every paper in the United States. Or more recently, the headlines from the Chicago newspapers, "Highjackers in medical work are assailed," by a prominent members of the medical profession, as incoming president of a medical organization. Another, "Spotlight of criticism on the profession as a cause of high cost of medical service." More recently, "Medical bootleggers." And these illustrations could be quoted indefinitely. I ask—is there any other profession that would try to correct their errors, if any, through such means? Do we not have sufficient private laundry facilities in our medical organizations and hospitals to take care of our dirty linen without waving it in the face of the general public?

I do not hesitate to declare that organized medicine has done more harm in this regard in lowering the esteem in which our profession was formerly held by the public than any and all other agencies openly employed against us. I do not approve, nor do you, of the objectionable individual advertising of the individual doctor, of his special skill, of his unusual operation, or such matter, but there is a middle ground that could be covered by news items, favorable and not critical of our profession. The press is as willing, I believe, to accept such publicity as unfavorable news. They want news.

Certainly one well known clinic has never, to my knowledge, despised favorable publicity and I admire their judgment and acumen in that regard. Favorable publicity of our local men and local hospitals helps us all. Unfavorable publicity hurts us all. It is about time we fought for each other instead of against each other. Every time I hear a special group in our profession undertake to promote themselves by unjustly roasting the rest of the profession in the public press, one local group criticise another group, or one member of our profession say derogatory things about another doctor, I think how useless, wasteful and pernicious it all is, and the sad thing about it is there is so little truth in any of it. I quote from the last bulletin of the American Medical Association: "There has been so much shooting at our profession by all sorts of marksmen, many of whom have used dum-dum bullets and other forms of ammunition forbidden under the rules of the game, that it is gratifying to one who still believes in the doctors of the land, to find an editorial here and there that gives some credit (to our profession) for sense, honesty and humanness." We will get sufficient opposition and unfavorable press comment by those opposed to our profession. We have been educated to the state where the only favorable publicity a doctor can read about himself, without blushing and dodging his colleagues, is his obituary.

Now, why is this so? It is not true of any other profession or even commercial organizations. A member of the sacred profession like the ministry may admit to a good friend, in private, that there is here and there an occasional brother who may stray from the "straight and narrow path," but I do not see the prominent members of their profession or their organizations bursting forth into print, and charging wholesale perfidy of their noble calling. No—they hold their trials in private and chastise their brethren in private, as the proven facts justify. Bankers do not vilify each other in public. Commercial organizations reprove and condemn unfair advertising on the part of any one of their members when such advertising hurts the entire industry, by supposedly boosting the individual advertiser. Does not even good taste dictate that family and professional quarrels, if any, be fought out in private? And then, strange to say, we are pained, grieved and hurt when the public take us at our own advertised valuation.

The public press every now and then features some sob story and I conclude from reading these that most every fair damsel who marries without love a wealthy man or otherwise loses her virtue, does so to get the money to pay for an operation of her dear mother or father. We know the absurdity of such stories but such is the food upon which our public is fed.

The Bar Association recently announced and is putting on a publicity campaign, frankly to the public, to enlighten them as to the aims and ambitions of the legal profession. I have confidence in our profession and confidence in the public, and, were our mutual problems better understood, I believe that much of the present criticism and suspicion directed at us would be cleared up.

We need more members of our profession in public office, national, state and local governments. It appears to have been the policy of our profession to raise the eyebrow and disparage unselfish service of our doctors in public office. We need and should encourage members of our profession to represent us where laws are made and public policies determined and not to refer to them as "political doctors." The legal profession has no trouble in getting any legislation they need, because they are on the ground with their personal contacts and votes.

Specialization.—Is there anyone who will deny that this feature of the practise of medicine has been overdone? When times were booming and money burning to be spent, the public took rather kindly to this innovation, as it flattered their vanity and gave them much topic of conversation at the afternoon tea table. Now things are different and the public are looking again for the extinct family doctor. The specialist should be a promoted or a postgraduate practitioner of years' experience in treating the body as a whole and the general ensemble not forgotten when his work is later confined to the consideration of a finely divided portion of the whole. The sudden bursting forth of the sprout of specialization within a short time of graduation, often leads me to conclude that the roots are sustaining nourishment from the top soil of ease and office practise at substantial fees, rather than dipping deep in the subsoil of experience, sacrifice and hard work, which after all tends to produce the most perfect flower of professional attainment. Certainly the well prepared and well grounded specialist is a necessity and a life saver for the general man, when special skill and knowledge is necessary in the diagnosis and treatment of obscure conditions.

The general public, in many instances, have been frightened by the elaborate details and the expense of the physical check-up, given in late years, especially by the clinic groups. They are often told by this specialist that the cardiograph is off a wave or two, by another specialist that the output of urea is deficient, by another that the nasal septum is deviated, etc., etc., until they finish their examination in fear and trembling. Strange to say they continue to live and, after a few months of worry, discover that life is still sweet and reasonably satisfactory. They are apt not to return as patients.

You remember the old campaign slogan, "What this country needs is a good five-cent cigar." I think what the public wants is a fairly good check-up of their essential physical findings for $5.00 by their family physician. If a patient comes into a doctor's office and states that he wants a complete examination and X-ray studies, I believe it would be good business, at that point, to tell him what he may expect in the way of a charge. If he then still wishes to go ahead, and many such examinations are necessary or may be discovered to be so by his physician, he is in no position to cry robber when he receives his bill.

Ultra-refinement in diagnosis and an untreated mental state of the anxious and worried patient, is the greatest factor that drives our patients to the various cults, who actually take the time and sometimes physical effort in doing something for the immediate symptoms, of which the patient complains. They universally breathe hope, courage and an infinite confidence in a cure. How often, indeed, this is the cure!

Dr. Angell, President of Yale University, in a recent address lamented the passing of the country doctor and said "that by no means least of the remedies he carried was the confidence he inspired. Even in these days of scientific knowledge of bacteria, surgery and the like, modern medicine must recognize the intrinsic significance of the emotional and psychic factors in human health. The quality of inspiring confidence the country doctor had in abundance, as he had the qualities of energy and devotion to a profession at once arduous and poorly recompensed. And fortunate it is that, away from the large cities, the old time country doctor has not been entirely supplanted by the specialist." I contend that the great bulk of our city doctors still come under the classification of the general practitioner and he is just as conscientious and certainly more capable than the old time country doctor, praised in song and prose. He just is not heard from to the same extent as is the specialist, and has both the good grace and common sense to keep from bursting forth into print in condemnation of his brethren. I have practised medicine in this city for twenty-five years, to be sure, most inconspicuously and possibly unworthily, but I am proud of the character, the unselfish services and the scientific skill of the average man with whom I have come in contact. I know of no other profession or group of men with whom I would rather associate or to whom more honor is deservedly due.

Ethics.—This is a word I wish we could drop from our professional vocabulary. It is to the general public like waving a red flag in the face of a bull. It should not be so. After all, ethics are necessary and are only a proper code that gentlemen of a noble profession should use in their daily intercourse with one another. But to the public, it is something mysterious, secretive, and a vague device, promoted by the members of the medical profession to better protect their own interests and to cover up their supposed mistakes.

If we wish to take the trouble, we could do much to explain this to the public, in our daily contact with them. I, personally, try never to use the word. For instance, it is easy to explain to a patient, if they want to change doctors, that it is a privilege well within their rights, and not to say, "Our ethics demand such and such a procedure." Rather tell them that the proper and polite thing to do, is to call up their doctor and tell him how they feel, pay his bill and then go ahead and employ the physician of their choice. This is no different from most other professions and many commercial institutions.

The greatest mistake a doctor makes, is when he tries to stay on a case where he is not wanted, or when someone else is desired in his place. A courteous attitude of the discharged doctor towards the patient and his family, in their request, would do wonders in raising us in public esteem. Sometimes the contrary attitude is employed by the physician and then ethics are blamed. Most complications arise when consultants are called, for the patient usually asks for a consultant with whom he is acquainted, or concerning whom he has heard good reports of his success in treating this particular condition with which the patient is affected. I have never had any great difficulty in sensing a situation in which I conclude that the patient would prefer to have the consultant take charge of the case and I do not hesitate to tell the patient and consultant that, if it is agreeable to both, I would prefer to have the consultant take charge. If the consultant shows evidence of promoting this change, I do not call him again.

We would do much nowadays, when so many patients of other doctors are seen in making out insurance examinations, X-ray reports in injury claims, etc., often in the absence of the attending physician, if we would take the trouble to say to the patient, "You are fortunate in having Dr. John Doe attending you, as he is an exceptionally fine doctor," or words to that effect. This sort of a compliment pleases the patient, surely helps the doctor, and, by helping the other fellow, we do most to help our profession as a whole. Suppose Dr. John Doe does not belong to the select few who stand at the head of our profession—still he belongs to the great majority of us who are just plain doctors. Even the law protects us common fellows by specifying that unusual skill is not essential in the treatment of a case, but that the practitioner need be able only to practise and to use the judgment of the average practitioner of medicine. Our supply of supermen is, after all, rather limited.

Hospitals.—After interviewing the superintendents of several of our local hospitals, I find that these organizations are generally facing serious problems, their occupancy being only from forty to sixty per cent of normal. Several years ago the city specialist decided that the more or less usual custom of joint fees with the country doctor was unethical and, therefore, should be abolished. This was done. The country doctors quickly retaliated, as is human nature, by putting a few beds in his home and his wife-nurse, with one or two other helpers, cared for his patients at home. Thus developed the country hospitals all over this northwest and they are good ones and their staffs are composed of well trained men. The public like this arrangement and our city hospitals have now about one-tenth of their former country patrons. In short, the country hospital and the country doctor have the business and we city doctors have our virtue. Both should be satisfied.

This was followed by the increasing tendency of the general public to accept, as part of their rights from the government, free treatment and hospitalization, by the charity or semi-charity institutions of the state and municipality. I have made an investigation of the public and private hospitals in Minneapolis and I find that the bed occupancy of the private hospital has been gradually declining over a period of the past ten years, while the tax-supported charity or semi-charity hospital beds have enormously increased. For instance, the University hospital admissions have increased in ten years, from 2,444 in 1921 to 6,437 in 1931. The General Hospital beds have increased ten to fifteen per cent in ten years and the outpatient department from two hundred a day to approximately four hundred and fifty a day. Figures on the Veterans Bureau Hospital are not of use, as they are not confined to local cases. We know the general situation in that regard and we know that the ability of the patient to pay his own way does not in the least bar his admission.

Then along comes our present depression to increase the private hospital vacancies and decrease the income of the doctors and nurses. The very poor are well provided for, as are the well-to-do. The average white collared man, who has an equity in his home and a small savings account, is the man who is now hit. Lincoln said, "God must have loved the common man for he made so many of them." These are the great proportion of the general public for whom we should make some effort to provide. I believe now is the ideal time for our hospitals and our profession to provide ways and means whereby this class of patient can be accommodated.

I believe that this should be done by an open advertising campaign to the public. That our hospitals should place a minimum charge upon their ward beds only, for the man with limited means. That nurses now out of employment and in actual want, and there are many such, could be hired by the hospitals to help care for these patients, if necessary, under group care and never one nurse confined to one patient, as is now our absurd custom. The entire financial arrangement should be handled by one wise individual at each hospital, who, through a frank talk with the patient and with outside investigation if necessary, would determine the fee that this individual could pay for his hospital service, together with the staff charge for such medical and surgical attention as might be needed. Again I say, I do not intend this service for anyone but the man who does not want to become a public charge, but who can pay a reasonable small fee for hospitalization and staff care. The man who has his regular job and adequate resources should be encouraged to take the most expensive accommodations at the hospitals, employ three private nurses and pay substantial medical fees.

Doctors are home owners and we must remember that any and all burdens we can lift off our charity hospitals, which will be used to their limits this winter in any case, will lighten the burden of taxes upon our homesteads, and will help keep the general public from becoming charity minded, and delay, at least, the present demand for socialization of medicine. Would not these same individuals, whom we may help at this time to retain their self respect, be the same public that we largely will deal with in the coming years when times become better? After all, how better can we help ourselves than by helping others, and by teaching the public the true principles of our profession, wrapped up and disguised as it may be by the manifold skeins of our so-called professional ethics and assailed as it is from within by self anointed and "holier than thou" critics.

Mount Sinai Hospital, New York City, has started what is called "a consultation service" for patients of moderate means. This plan has many desirable features which we might well consider.

Medical Organizations.—Of these we certainly have aplenty, but they are mainly concerned with the scientific side of the practise of medicine and too little concerned with the economic problems, which should go hand in hand with the science of medicine. I quote from the "Medical Profession and the Health Department," edited by Dr. A. J. McLaughlin of the United States Public Health Service. "We speak of the organized medical profession but its organization is little more than provision for periodic meetings for some reading and discussion of papers on scientific subjects. An exaggerated sense of ethics makes many physicians shrink from anything like business organization; yet organization on a business basis, provision for clinic facilities, regulation of fees on a sliding scale basis according to income are absolutely esential, if State medicine is to be prevented."

I would like to see our own local organizations devote more time and study to economic conditions affecting our profession and there should still be sufficient time left for the consideration of the scientific. The old instructions as to how to "skin a cat" began thus, "First, catch your cat." Right now we might well consider how to catch again the confidence of the public. This will be best accomplished when the general practitioner, who makes up the bulk of our profession, more often takes the helm of our medical organizations. We have before our ethics committee now and then numerous minor infractions of our so-called ethics. I woud like to see the publicity traducers of our profession, whether individuals or organizations, brought before organized medicine and asked to prove their blanket accusations against our profession or be made to get out of organized medicine.

I have never observed that a bird got any great degree of satisfaction out of fouling his own nest, even if it did produce some discomfort to his associates. The old timers will remember one morning during a presidential campaign, observing upon the billboards, all over the country, this slogan, "Let's be through with wibble and wobble." I would like to see on every bulletin board of every medical meeting place in this country the following paraphrase of the above, "Let's be through with squibble and squabble." One of our old and respected physicians once made a remark to me, that holds a world of truth. He said, "I have never, to my knowledge, profited by any misfortune or ill luck of any of my associates, but I do know that I have been helped by any and all of their successes."

Our national and local organizations are fighting a splendid and unselfish battle to stop the plea for additional hospital beds for the care of disabled veterans and the government employees generally, and in the place substitute the care of these patients in private hospitals. Our medical literature is full of this plan and you are well aware of the situation. But not so the general public. The present time appears to me to be the psychological moment to carry this campaign to the general public, who are now tax minded as never before. The work being done by our organizations through the American Legion is effective, no doubt, but the taxpaying general public would be with us to a man, were the situation known. This opportunity may never again occur.

The general taxpayer, as well as the Legionaire taxpayer, of which I am one, is entitled to this information and that quickly. I surmise that our representatives in Congress would welcome hearing from the general public at this time, in spite of the opportunity for political patronage in their districts, were another unit to be obtained there. We have enough doctors in the American Medical Association belonging to civic organizations to put a stop to this program in thirty days, were they let loose.

The constant rise in dues in our medical organizations is causing an increasing number of resignations, when organization is needed now more than ever. Would not more attention to economic conditions and consideration of practical problems affecting the profession help to hold our members together and make them feel that our organization is alive and interested in the welfare of the individual members, economically, as well as scientifically?

RÉSUMÉ

1. Can we not as a profession, by our better

conduct, organized effort and study along economic lines, improve our status and that of the hospitals and nurses with the general public and at the same time render a better and more efficient service?

2. Private medicine stands at the bar of public opinion awaiting their verdict. State medicine is impatiently hoping for a verdict of "Guilty."

3. Self appointed, self serving and self advertising character witnesses out of our own profession are helping the jury to decide against us.

4. As one of the inconspicuous attorneys for the defense, I plead that the great majority of private physicians, in all branches of our profession, are doing their work honestly, conscientiously and capably and any substitute of socialized medicine will result in deterioration of service and profession.

5. As a profession let's cheer up and boost, criticize not at all in public, and spank, if necessary, in private.

THE TREATMENT OF CLUB FEET (TALIPES EQUINO VARUS) IN INFANTS

C. C. Chatterton, M.D., F.A.C.S.
Saint Paul

THE treatment of club feet has been one of the oldest requirements of surgery. Many methods have come and gone, and in careful observation of the literature, while the principle of treatment is somewhat constant, the real course of treatment has not been definitely outlined nor has it been constant in procedure.

Nothing new is claimed for the method outlined, but the results of such procedure have been so much more gratifying and universally more satisfactory than other methods, after years of trial, that it is always used in infants.

The different methods now in use, some quite satisfactory as to end-results, and others perhaps not well carried out with most unsatisfactory endings and quite constant atrophy, limited motion and only partial correction of deformity, I believe make this method worthy of attention.

In many instances, with much less trouble, it is possible to get as an end-result a foot that, at the expense of motion, atrophy, and bony displacement, looks well when covered by a shoe. In a few cases this may be the only end-result possible. The method outlined is applicable to practically all cases as beginning treatment and has the following advantages:

1. Correction of deformity.
2. Preservation of motion of foot.
3. Prevention of marked atrophy of leg and foot.
4. Use of absolute retentive apparatus and dressings for the least possible time.
5. Avoidance of extensive operation.
6. Simplicity of procedure.

The various degrees and types of talipes equino varus are many, but for treatment with prognosis and end-results, my cases are divided into three classes:

1. Cases of easy correction with or without some bony deformity, excluding bony fusion or absence of bone.

2. Cases of difficult correction with definite contraction of tissue and with or without some bony deformity, excluding bony fusion or absence of bone.

3. Cases with definite contraction of soft parts, bony fusion of joints, absence of bone or hypertrophy of bone.

Cases in Class 1 are common and in this class a cure is expected without surgery of any sort, and usually the case is cured before the weight-bearing period.

Cure is expected in cases under Class 2 with the aid of only a simple operation, the child being free from all apparatus before the age of two years.

Cases in Class 3 are seldom met, and while the general contour of the foot may be greatly benefited by outlined treatment, extensive surgical procedures may of necessity be used to secure a serviceable foot.

METHOD OF TREATMENT

To successfully carry out the treatment, some experience in the use of the plaster-of-Paris bandage in the manufacture of a splint is required. A willing and intelligent mother or nurse and of necessity much patience, time and coöperation are also required.

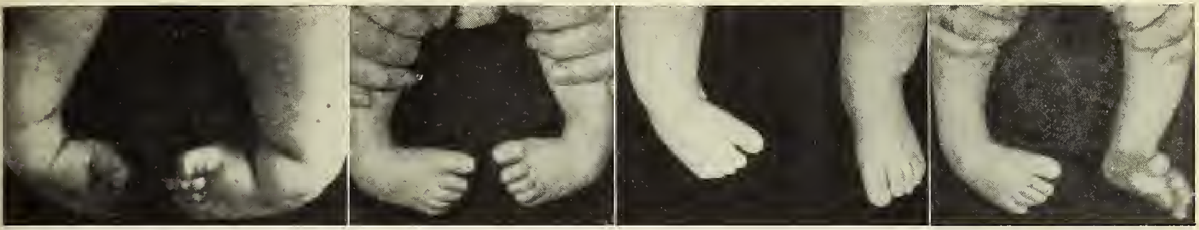

Fig. 1. Typical examples of types of talipes equino varus in infants at first examination.

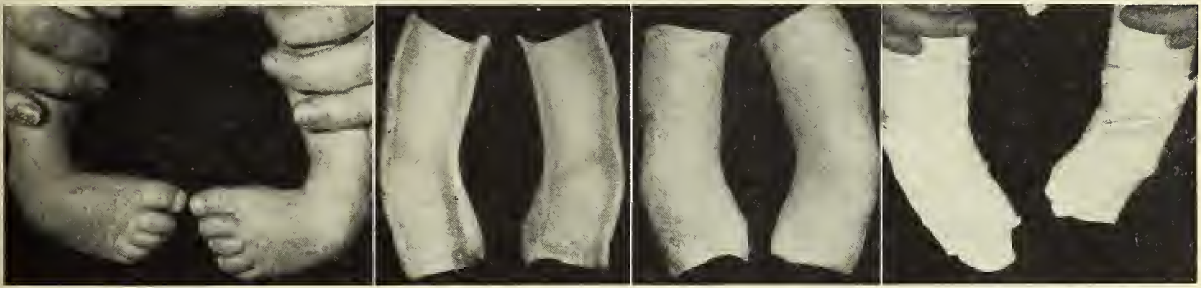

Fig. 2 *(left)*. Typical talipes equino varus; *(center)*, plaster splints ready for application; *(right)*, plaster splints as applied by mother with bandages.

Treatment proper is begun usually at the end of the second or third week of the infant's life. Some gentle manipulation and massage can be used to advantage under proper instruction even before this time. The infant should be gaining in weight and healthy when treatment is started.

The surgeon's part is essentially an office procedure and consists of the manufacture of splints that can be removed and reapplied in simple manner by the mother or nurse. Materials other than plaster-of-Paris have been used, but, because of its availability, plaster-of-Paris has been my choice. Metal splints, moulding felt or dental vulcanite can be used.

Detail of Manufacture of Plaster Splint.—The infant's foot and leg are covered with oil and the varus deformity is gently and firmly overcome as much as possible without force. A lead strip ⅛ inch thick and ¾ inch wide is moulded over the anterior surface of foot and leg and the parts from tip of great toe to knee are carefully and firmly encased in the plaster. Only the varus deformity is overcome by the first application and the foot is held in the corrected position until the plaster is set. Usually only two or three bandages two inches by six feet are used. The cast is then cut over the strip and the cast and lead removed and at once a large portion, almost the anterior half of the cast, is cut away, leaving a small portion covering the great toe. The outer side is cut away enough so that the heel can be slipped into the well defined sulcus. The splint is made smooth, dried, and then painted with paraffin or shellac.

In the average case three or four dressings at intervals of six weeks are necessary to overcome the varus. We feel that after the varus has been overcome, the os calcis has gone back under the foot, the neck of the astragalus is pointing in the normal direction and the body of the astragalus is under the tibia. The bony deformity in the average case is in a position to rapidly approach normal alignment.

The mother or nurse is instructed to apply a stocking or stockinette to the baby's foot. At the office, the splint is applied several times until the mother is sure of the method. A cloth elastic Ace bandage or flannel bandage covers the cast, foot and leg to hold the splint in the proper position. The splint is removed not less than four times daily for manipulation, stimulation, massage, and exercise. Some twenty-five to fifty definite manipulations for overcoming the varus are taught. Touching the foot with a brush or the finger-tips is used to stimulate muscular contraction. Massage in the form of gentle firm motion over the leg and foot and over the contracted parts is given three to five minutes four times daily. The splint and stocking are removed at bath time for an hour for normal exercise and motion of the foot.

Treatment after Varus Deformity has been Corrected.—Varus deformity is considered as overcome when the foot and great toe can be held out easily ten to fifteen degrees beyond a straight line from center of leg.

Treatment then consists as follows:

1. A splint is made in same manner, but the inner side is left more open and the outer side comes up over the malleolus, a deep sulcus being left for the heel.
2. The mother or nurse are instructed as to:
   a. Application of the splint.
   b. Manipulation to include stretching of the plantar tissue and the tendo achillis group.
3. Massage is continued as before.
4. The apparatus is removed as before at the bath period.
5. Muscle stimulation is produced by finger or brush to especially invite contraction of the peronei muscles and the extensors of the toes.

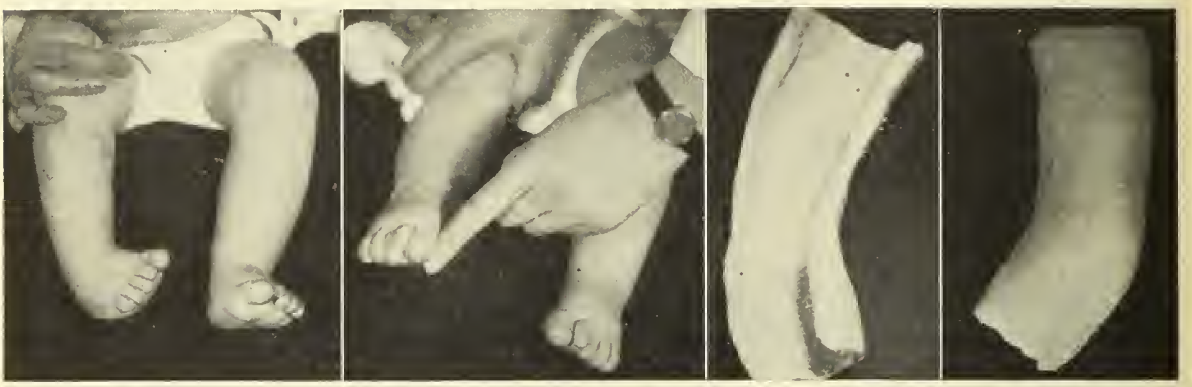

Fig. 3. Typical talipes equino varus showing correction of varus at time of making of first splint. Third and fourth views show splints used in this case.

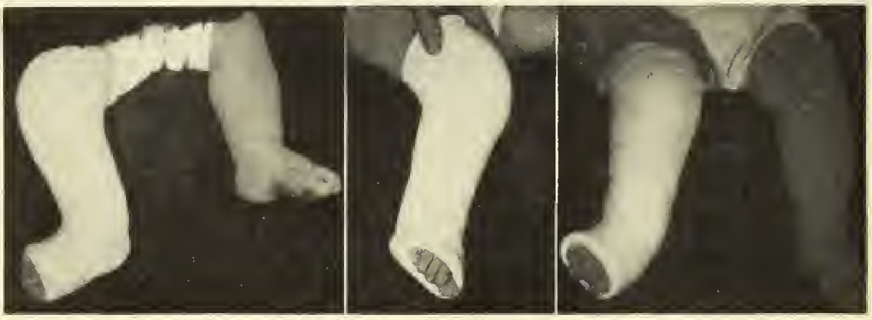

Fig. 4. Examples of correction of deformity at time of minor operation. Foot is in position of calcaneous valgus, cast extending above knee to prevent or correct torsion of tibia.

Progress is usually slower during this period, but the foot is in such a position that deformity of the bones and joints will not occur.

This period continues until the child shows signs of standing or weight-bearing. Creeping and crawling are prohibited because frequently the tibia is likely to become twisted internally by the position usually maintained by the foot while this exercise is in progress.

Usually four or more splints are required for this period.

If at this time torsion or bowing of the tibia is present, one or two splints are made long enough to include at least four inches of the thigh and encircle the thigh slightly more than half, continuing the correction of the equinus and also keeping the foot in valgus to overcome any torsion.

TREATMENT OF INFANTS IN EARLY WEIGHT-BEARING PERIOD, NINE TO FIFTEEN MONTHS

1. In cases well corrected.

Many of these patients stand and bear their weight perfectly and use a splint usually extending above the knee at this period only when sleeping. Often the shoe is wedged on the outer sole ⅛ to ⅜ inch to overcorrect the position of the foot. A small side iron brace in used in cases where muscle power, especially of the peronei is slow in developing. Often only observation during this period is necessary, as many are cured long before the advent of the weight-bearing period.

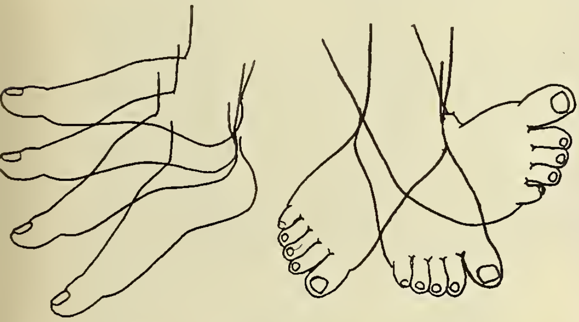

Fig. 5. Schematic drawings showing gradual correction of equinus deformity.

2. Cases not corrected at weight-bearing period.

If either the varus or equinus deformity is not correct at the time the child shows signs of weight-bearing, the deformity must be corrected by surgical means. In all cases where there is no bony fusion, nor hypertrophy of bone present, the deformity is of the soft parts and can be overcome, after months of the treatment outlined, by simple surgical procedure.

In non-corrected cases at this age we find a contracted tendo achillis and plantar fascia the prime factors in preventing complete correction by the splinting, manipulative, massage and exercise method.

The child is not allowed to bear weight on a foot that is not well overcorrected both as to the varus and equinus deformity. Weight-bearing with the foot in an overcorrected position is most valuable in changing the shape of the deformed bones and joints, and walking even a few weeks with the foot in an undercorrected position will often add months to treatment and may defeat the object of this simple procedure.

OPERATIVE PROCEDURE IN CASES NOT RELIEVED BY SPLINTING, MASSAGE, MANIPULATION AND EXERCISE AT WEIGHT-BEARING AGE, NINE TO FIFTEEN MONTHS

In cases where manipulation, splinting, massage and exercise have not overcorrected the de-

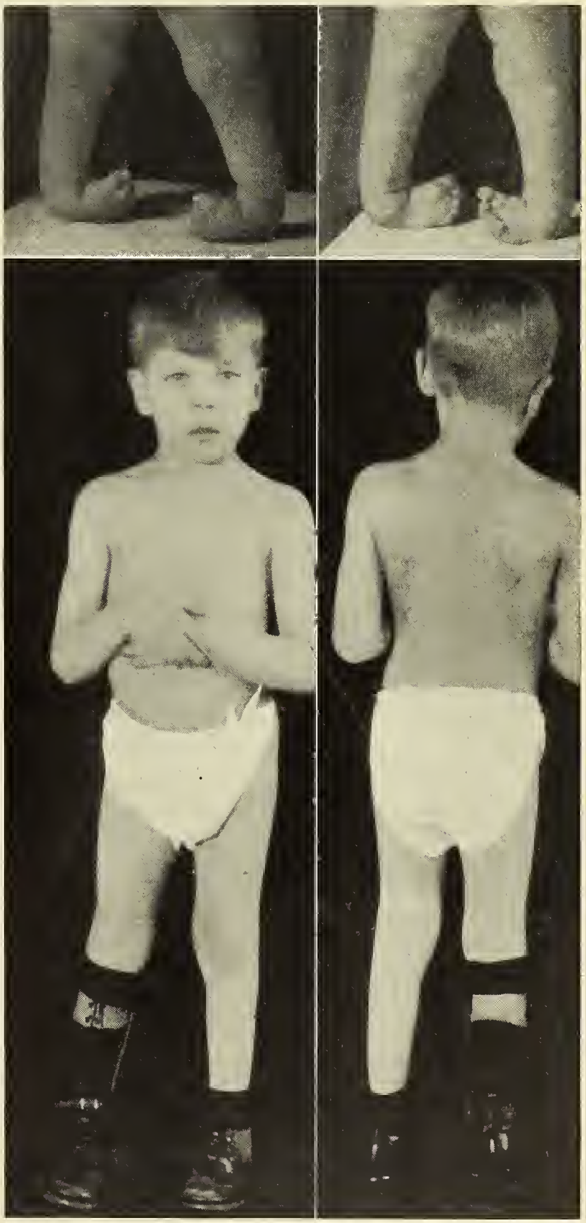

Fig. 6. Typical club feet improved by simple procedure, wearing side iron brace with outer edge of shoe thickened, right foot.

formity, it is usual that contraction of the soft parts is found. The contracted tendo achillis group of muscles is the factor to be overcome in the equinus deformity. This contraction is relieved by the subcutaneous method of tenotomy and myotomy. The contracted group is divided high up near the junction of the muscle and the beginning of the tendon. Tension is maintained while the tenotome saws the muscle and tendon in several places.

The plantar fascia may tend to prevent correction of the equinus and varus and again by subcutaneous incision with tenotomy just anterior to the insertion on the os calcis, the fascia is lengthened.

Only rarely are the flexor tendons of the toes lengthened by subcutaneous section near the base of toes.

The foot is gently manipulated into an overcorrected position. No great manipulative force is used, and extreme overcorrection and manipulation are inadvisable and not necessary.

Sterile gauze is placed over the wounds, sheet wadding or a stockinette is applied and a plaster dressing which is worn for six weeks. The plaster cast extends from the base of the toes to three inches above the knee, the foot being held in an overcorrected position of calcaneus valgus.

Weight bearing is encouraged two weeks after the operation.

A second plaster is applied from the toes to the knees and worn for four weeks. Weight-bearing and walking are encouraged and the foot still held in calcaneus valgus position.

After removel of the second cast, a walking apparatus, with a wedged shoe and, if the muscles are weak, a side iron brace, is used with continued massage, manipulation and exercise. Creeping is prohibited because of tendency to cause torsion of the tibia.

Observation of a case is important and the child is seen at six-weeks to two-months intervals until the age of two or assurance that the deformity is remaining corrected.

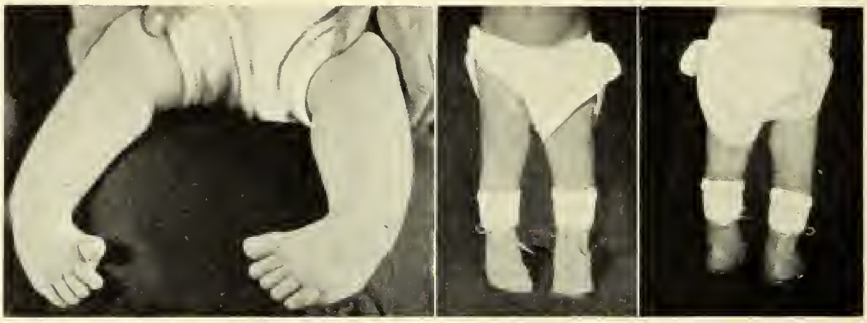

Fig. 7. First view—typical club feet. Second and third views—application of wedged shoes when child begins to walk.

The infant with marked bony defects obvious to external and X-ray examination is only the rare case and not in the usual class under discussion in this paper, but is in my experience best treated by this harmless method, prolonging the bony operation until the child is of such age that the least possible damage is done to bone and soft parts by operation necessary to correct such deformity.

Under no circumstances is the infant dismissed as cured until after the foot has been used for walking several months. Walking or weight-bearing is not allowed until the foot is in a normal, overcorrected position, as weight-bearing with the foot in proper position causes change in the bones and shape of bones not possible to obtain in any other manner and is most important in perfecting the cure.

With certain other methods where forced manipulation and early operation require absolute retentive apparatus, it is not possible to remove the apparatus for daily manipulation from the time of operation until after the weight-bearing age.

Coincident with long continued absolute retentive apparatus, marked atrophy, inability to use muscles, and loss of motion are the usual results: while by the method described, absolute retentive apparatus is used only during the first ten weeks of weight-bearing and avoids in the greater part marked changes and disability as the result of the methods just mentioned.

The successful treatment of club foot is not easy and the fact that its routine is not well understood is evidenced by numerous examples seen not only at public and state institutions, but in private practice, where deformity, marked atrophy, disability, limited motion, scars, contracted bands and pressure sores with the usual history of radical operations and severe manipulation even in the first few weeks of life, with history of long continued retentive apparatus as the causative factors in the poor and characteristic end-result.

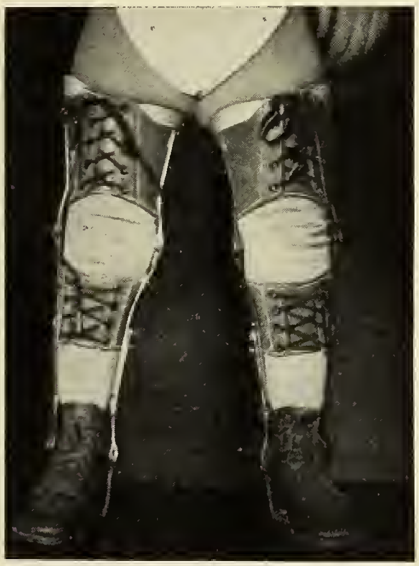

Fig. 8. Typical braces with joints at knee and ankle, used when torsion of the tibia is marked.

I submit this simple method well knowing if faithfully carried out by surgeon and parent, at least it is a method that has, in my experience, proved most satisfactory without the possibility of the above named common experiences which usually hinder the average chance of a good functional result.

A STUDY OF THE INCIDENCE OF AURICULAR FIBRILLATION*

Harry L. Smith, M.D.
Rochester, Minnesota

AURICULAR fibrillation (delirium cordis, or pulsus irregularis perpetuus, total irregularity, or irregular irregularity) continues to be the most frequent of the significant forms of cardiac arrhythmia.

A study has been made of the records of 1,045 consecutive cases of auricular fibrillation, to ascertain the incidence of the etiologic factors or the conditions commonly and remotely associated with auricular fibrillation. To all intents and purposes these conditions may be considered etiologic. The diagnosis of auricular fibrillation has been made by means of the electrocardiogram in each instance. In most of these cases the fibrillation was chronic. A small proportion of the patients had intermittent auricular fibrillation; this was especially true of those who had hyperthyroidism.

It will be noted, in Table 1, that chronic rheumatic endocarditis with mitral stenosis was the clinical diagnosis most commonly associated with auricular fibrillation. That held true if exophthalmic and adenomatous goiter with hyperthyroidism each was listed under a separate head, and if coronary and hypertensive heart disease each was put in a different group. However, if exophthalmic goiter and adenomatous goiter with hyperthyroidism were classified together under one head, and if hypertension and coronary heart disease were listed under one head, chronic rheumatic endocarditis with mitral stenosis came third in the list (Table 2). Considered from this viewpoint, hypertensive and coronary heart disease heads the list of causes of auricular fibrillation, or of conditions associated with it, with a frequency of 33.9 per cent. Hyperthyroidism was a close second, with 32 per cent and chronic rheumatic endocarditis with mitral stenosis came third with 22 per cent. In Table 2 it will be noted that hypertensive and coronary heart disease taken together, hyperthyroidism, and chronic rheumatic endocarditis with mitral stenosis were the three most common causes of auricular fibrillation. Next in frequency came a group of cases in which the etiology could not be determined. In this group there were eighty-one cases, in sixty-one of which there were cardiac symptoms, and in twenty, no cardiac symptoms other than irregularity. A few of the patients whose cardiac action was irregular were not even aware of it. Cardiac symptoms, when present, were in some cases very mild; in others, they were those of severe congestive failure.

The remaining classifications in Table 2 are self-explanatory. However, concerning the ninth classification: it is generally known that auricular fibrillation is a relatively rare accompaniment of cases of subacute bacterial endocarditis. Why this should be is not explained. One would naturally expect it to occur commonly, because a relatively large number of cases of subacute bacterial endocarditis is engrafted on old, especially on mild, chronic rheumatic endocarditis with mitral stenosis, and auricular fibrillation is frequently associated with chronic rheumatic endocarditis with mitral stenosis; in fact, auricular fibrillation accompanies this condition in the highest relative incidence, as will be seen when Table 3 is analyzed.

It appears, from Table 2, that coronary and hypertensive heart disease, hyperthyroidism, and chronic rheumatic endocarditis with mitral stenosis are the three most common causes of auricular fibrillation. But this table was constructed on a basis of consecutive cases of auricular fibrillation seen at the clinic. However, more cases of hypertension and coronary disease were seen than were seen of cases of hyperthyroidism, and so on. It was desired to determine the actual proportion of cases of hypertensive and coronary disease, of hyperthyroidism, of mitral stenosis, and so forth, in which auricular fibrillation would be found. Therefore, a group of 100 cases of chronic rheumatic endocarditis with mitral stenosis, taken consecutively as the patients concerned registered at the clinic, was studied (Table 3). In a small proportion of them, necropsy was performed. There were

TABLE 1

RELATIVE INCIDENCE OF ETIOLOGIC DISEASES IN 1,045 CASES OF AURICULAR FIBRILLATION

	Incidence	Per cent
1. Chronic rheumatic endocarditis with mitral stenosis	230	22.0
2. Exophthalmic goiter	174	16.0
3. Coronary disease alone	168	15.0
4. Adenomatous goiter with hyperthyroidism	161	15.0
5. Hypertensive and coronary heart disease	105	10.0
6. Hypertensive heart disease alone	82	7.8
7. Indeterminate*	81	7.7
8. Pericarditis	16	1.5
9. Chronic rheumatic endocarditis with aortic stenosis	9	0.8
10. Aortic insufficiency (rheumatic)	9	0.8
11. Syphilitic aortitis	8	0.7
12. Subacute bacterial endocarditis	2	0.019
Total	1,045	

*The diagnosis was auricular fibrillation, but the etiology was undetermined.

TABLE 2

RELATIVE INCIDENCE OF ETIOLOGIC DISEASES IN 1,045 CASES OF AURICULAR FIBRILLATION*

	Incidence	Per cent
1. Hypertensive and coronary disease	355	33.9
2. Adenomatous goiter with hyperthyroidism and exophthalmic goiter	335	32.0
3. Chronic rheumatic endocarditis with mitral stenosis	230	22.0
4. Indeterminate	81	7.7
5. Pericarditis	16	1.5
6. Chronic aortic endocarditis with aortic stenosis	9	0.8
7. Chronic rheumatic aortic endocarditis with aortic insufficiency (rheumatic)	9	0.8
8. Syphilitic aortitis	8	0.7
9. Subacute bacterial endocarditis	2	0.019

*Items 3, 5 and 6 of Table 1 combined as item 1 of this table; items 2 and 4 of Table 1 combined as item 2 of this table.

twenty cases of auricular fibrillation. In a study of another series of forty-nine cases of chronic rheumatic endocarditis with mitral stenosis, in all of which necropsy was performed, auricular fibrillation occurred in twenty cases (40 per cent). I think the difference between twenty and forty is about what would be expected, because the longer any cardiac disease exists, and the more severe it is, the more likely it is that fibrillation would occur. A patient who has come to necropsy obviously has had the disease for the maximal time that is compatible with life for him. This is probably why the frequency of auricular fibrillation in the forty-nine cases in which necropsy was performed was twice as high as in the group of 100 cases, in few of which necropsy was performed.

In a group of 205 cases of adenomatous goiter with hyperthyroidism (Table 3), selected and studied the same way, it was found that auricular fibrillation occurred in twenty-nine cases (14 per cent). The next group studied was 144 cases of chronic adherent pericarditis; in this group, only cases in which necropsy was performed were used, because of the high percentage of error in the clinical diagnosis of this condition. In drawing conclusions based on a series of cases in which neccropsy was performed with a series in which the data are obtained mainly by clinical means, this fact must be kept in mind. It is to be expected that in the series of cases in which necropsy was performed, the percentage of auricular fibrillation will be higher. There were several cases in which an associated valvular disease existed, especially mitral stenosis. This, too, would probably account for the high proportion of cases of auricular fibrillation. These two reasons—that necropsy was performed and that mitral endocarditis and mitral stenosis were associated—probably explain why this group comes third in Table 3. The remaining entries in Table 3 require no comment, except to say that in the 113 cases of pericarditis with effusion, necropsy was performed in each case.

In Table 3, it will be noted that the incidence of auricular fibrillation among patients who had

TABLE 3

INCIDENCE OF AURICULAR FIBRILLATION IN CONSECUTIVE CASES OF DISEASES WHICH MAY CAUSE AURICULAR FIBRILLATION

Diagnosis	Cases	Auricular fibrillation	
		Incidence	Per cent
Chronic rheumatic endocarditis with mitral stenosis*	100	20	20.0
Adenomatous goiter with hyperthyroidism	205	29	14.0
Chronic adhesive pericarditis**	144	18	12.0
Aortic stenosis	100	8	8.0
Exophthalmic goiter	203	10	4.9
Aortic insufficiency (rheumatic)	100	4	4.0
Syphilitic aortitis	100	4	4.0
Hypertensive heart disease	100	4	4.0
Pericarditis with effusion	113	4	3.5
Coronary sclerosis	100	3	3.0
Congenital heart disease	100	2	2.0
Subacute bacterial endocarditis	100	1	1.0

*In another series of forty-nine cases in which necropsy was performed auricular fibrillation occurred twenty times (40 per cent).

**Necropsy performed in all cases.

TABLE 4

INCIDENCE OF AURICULAR FIBRILLATION IN CASES REPRESENTING A PARTICULAR AGE GROUP

Diagnosis	Cases	Age-group	Auricular fibrillation	
			Incidence	Per cent
Adenomatous goiter with hyperthyroidism	50	50–60	7	14
Exophthalmic goiter	50	50–60	5	10

adenomatous goiter with hyperthyroidism was almost three times as high as that among patients who had exophthalmic goiter. It was believed that the reason for this was that adenomatous goiter with hyperthyroidism generally occurs among people who are older than those who have exophthalmic goiter. Older people are more likely to have fibrillation from any given cause than are younger persons. Consequently it would be expected that the incidence of auricular fibrillation would be higher in older persons who had either adenomatous goiter or exophthalmic goiter. To determine if this were true, I took a group of fifty cases of adenomatous goiter with hyperthyroidism among patients fifty to sixty years of age (Table 4) and compared the incidence of auricular fibrillation in this group with that in the correspoding group recorded in Table 3. The percentage incidence in the two groups was the same. The reason presumably was that the patients with adenomatous goiter with hyperthyroidism recorded in Table 3 tended to be elderly. However, when a like comparison was made between the corresponding groups of patients who had exophthalmic goiter, the incidence of auricular fibrillation in the group of fifty (Table 4) was found to be considerably higher than that in the group recorded in Table 3. The reason probably was that the patients with exophthalmic goiter who are represented in Table 3 tended to be much younger than fifty to sixty years. It would appear (Table 3) that auricular fibrillation is associated with adenomatous goiter with hyperthyroidism in a higher incidence than it is with exophthalmic goiter. It is believed as has been indicated that this is true mainly because adenomatous goiter with hyperthyroidism tends to afflict older persons than does exophthalmic goiter. There is another factor which possibly may influence this high incidence of auricular fibrillation in association with adenomatous goiter, and that is that patients with adenomatous goiter with hyperthyroidism probably have had their hyperthyroidism continuously over a longer period before they were operated on than patients with exophthalmic goiter, because exophthalmic goiter, as a rule, is a more urgent condition.

The incidence of auricular fibrillation found in this study has varied somewhat from that of other workers, although the results obtained compare fairly closely with those of McEachern and Baker. In their study they found that rheumatic heart disease constituted the largest single group of cases, with a percentage of 34.4, but they classified hypertension and arteriosclerosis under separate heads. Hyperthyroidism constituted only 7.5 per cent of their series, whereas it accounted for 32 per cent of my series.

SUMMARY AND CONCLUSIONS

In a series of 1,045 consecutive cases of auricular fibrillation, the associated or causative conditions which occurred in highest incidence were hypertensive and coronary heart disease (Table 2). The incidence of this combined condition was represented by 33.9 per cent. Hyperthyroidism occurred second in frequency, with 32 per cent. Mitral stenosis (mitral endocarditis with stenosis and insufficiency) occurred third in frequency, with a percentage of 22. However, among consecutive cases of diseases which are known often to be accompanied by auricular fibrillation, mitral stenosis (mitral endocarditis with stenosis and insufficiency) was found to be accompanied by auricular fibrillation in higher proportion than any of the other diseases (Table 3).

ANGINA PECTORIS: HISTORY, ETIOLOGY AND MECHANISM*

Fredrick A. Willius, M.D.
Rochester, Minnesota

ANGINA pectoris has been afforded the distinction of being considered a disease by some observers and a symptom by others. Owing to the fact that angina pectoris comprises a group of symptoms and results from several pathologic processes, present-day nomenclature has designated the term anginal syndrome, as descriptive, but whenever possible the name of the etiologic disease is used. For example, one speaks of the anginal syndrome due to coronary sclerosis, or the anginal syndrome due to atresia of the coronary orifices secondary to syphilitic aortitis. By this practice the diagnosis of cardiac diseases is made with much greater accuracy and comprehensiveness.

The scope of this paper does not permit detailed consideration of the historic background of angina pectoris, and therefore only some of the most important contributions will be mentioned, which in reality are landmarks in the progress of knowledge of this condition. In 1700, Drelincourt recorded what appears to have been the first recognition of coronary sclerosis, and three years later Bellini associated myocardial disease with coronary sclerosis. In 1768, Heberden wrote his description of the anginal syndrome so accurately and completely that it stands today as a masterpiece. In 1794, John Hunter described the disease which afflicted him in a manner possible only to one who had experienced the pangs of angina pectoris. In 1799, Parry, a contemporary of John Hunter, recognized coronary sclerosis clinically. Parry was intimately associated with John Hunter's physician, Jenner. In 1815, Hodgson called attention to the relationship of sudden death to coronary disease. In 1827, Adams described what certainly was cardiac infarction, but apparently he did not appreciate its cause or origin. In 1850, Creveilhier gave the first comprehensive review of coronary thrombosis and cardiac infarction. In 1889, Huchard presented a dissertation on angina pectoris, and reviewed the current historical theories. He related angina pectoris to coronary disease and to aortic disease. In 1896, Dock was the first observer in America to describe coronary thrombosis, and in 1912, Herrick clearly described the condition and reported the case of a patient who recovered. In 1914, Mackenzie emphasized the part played by the coronary arteries in angina pectoris, and called attention to fatigue of the heart muscle in the causation of the attacks. In 1915, Allbutt refuted the hypothesis that coronary disease is a cause of angina, and was of the opinion that the aorta was solely concerned. He believed that irritation of the nerve endings in the adventitia, particularly of the first portion of the aorta, was the cause of the painful seizures.

---

*From the Section on Cardiology, The Mayo Clinic, Rochester, Minnesota. Read before the Minnesota Society of Internal Medicine, St. Paul, Minnesota, November 9, 1931.

This hypothesis for a time received widespread recognition, but in succeeding years attention has been directed, again, to the coronary circulation.

ETIOLOGY

The anginal syndrome is preëminently identified with coronary arterial disease. Sclerosis of the coronary arteries is the pathologic process most commonly encountered, and is virtually limited to the larger branches. The involvement may be extensive or localized with formation of plaques; it may be obliterative, or it may permit the arteries to remain relatively patent.

Coronary thrombosis and embolism are virtually always accompanied by the anginal syndrome; the pain is more severe and of longer duration and secondary phenomena occur that are absent under other conditions. This fact makes untenable the arguments against the hypothesis that coronary disease is etiologic.

Atresia of the coronary orifices associated with syphilitic aortitis is usually attended by the anginal syndrome. Stenosis of the aortic valve and orifice frequently is attended by painful cardiac seizures, subjectively indistinguishable from those occurring in the course of coronary disease. Narrowing of the aortic orifice renders the coronary circulation imperfect, although the coronary arteries may be normal structurally. Rarely, large vegetative lesions of subacute bacterial endocarditis of the aortic valve may impinge on the coronary orifices and be the cause of the anginal syndrome.

Severe anemia, primary or secondary, may result in imperfect nutrition of the heart and the physiologic counterpart of coronary disease is produced. In certain cases, severe and prolonged paroxysmal tachycardia is attended by the anginal syndrome. Extreme cardiac acceleration is accompanied by a diminished volume output per beat and in attacks of great acceleration, both systolic and diastolic blood pressure fall. The drop in diastolic pressure may be considerable, and it may be impossible constantly to maintain adequate coronary circulation.

The anginal syndrome, then, is primarily dependent on absolute or relative insufficiency of the coronary circulation, as has been noted. When the coronary circulation becomes insufficient, anoxemia of the myocardium occurs, and is one of the significant factors in cardiac fatigue. Associated metabolic disturbances are not definitely understood.

Spasm of the coronary arteries as a cause of the anginal syndrome received considerable attention at the beginning of the present century, and although its existence, and the possibility that it is causal in certain cases cannot be denied, doubt must still be held concerning it.

The mechanism whereby myocardial anoxemia influences the nerve endings to produce pain is not clearly understood, but probably is similar to the production of cramp in voluntary muscles during fatigue.

After the onset of the initial anginal attack, the nervous mechanism appears to become sensitized, so that an arc of abnormal distribution of stimuli becomes established. In the spinal cord a region becomes irritable, which under normal conditions has not been particularly irritable; it may become highly sensitive, in a manner similar to that in which certain portions of the lumbar part of the spinal cord become irritable in normal subjects.

A sensitive, nervous constitution appears to be significant in determining not only the occurrence but the continuation of the anginal syndrome.

TREATMENT OF ASTHMATIC BRONCHITIS WITH IODIZED OIL*

JOSEPH H. TAYLOR, M.D.
Minneapolis

WHILE the treatment of bronchial asthma due to extrinsic causes is theoretically a matter of removing the offending cause, or of specific desensitization, experience has shown that there is a large group of individuals who do not yield to such treatment or in whom such causes cannot be found. This group includes the cases of so-called "bacterial asthma" or of "asthmatic bronchitis" in which bacterial invasion of the bronchial tree has occurred. Progression from simple asthma to asthma complicated by infection, with bronchitis and emphysema, is not uncommon.

Rackemann[1] states that bacteria can produce asthma in three ways: (1) through a definite allergic effect without reference to other allergens; (2) by modifying sensitiveness to other allergens so that symptoms are produced following exposure to them; and (3) by intensifying the attack of asthma which has started from any cause.

In this group of cases of asthmatic bronchitis are those whose asthma occurs after some acute respiratory infection and is not related to any change in environment or manner of living. The amount of secondary infection may be determined from the cough, sputum, and wheezing present between attacks. The sputum is likely to be thick and purulent in severe cases. Cough is quite marked at the onset of the attack, as contrasted with uncomplicated asthma in which it is present only at the end of a paroxysm.

Various measures of non-specific therapy, such as the use of expectorants, autogenous vaccines, ultra-violet irradiation, X-ray therapy, surgical removal of the sympathetic ganglia, and bronchoscopy with local applications, have been tried with varying results.

The instillation of iodized oil into the bronchial tree as a method of diagnosis and treatment in cases of bronchitis and bronchiectasis has been carried out by Ochsner[2] in more than 1,500 cases, and he has found evidence of some degree of bronchial dilatation in over 90 per cent of these. He found that the iodized oil was of distinct therapeutic value in these cases. The number of organisms in the sputum as determined by actual count was found to decrease progressively. The tendency of lipiodol to cause rapid healing has also been noted in cases of empyema by Ransohoff and Heiman,[3] who injected lipiodol into the residual cavity after treatment of empyema by aspiration drainage and Carrel-Dakin instillations. Similar results were found when it was injected into the seminal vesicles by Belfield and Rolnick.[4]

Caulfield[5] in a similar way has injected gomenol, an essential oil extracted from the Melaleuca plant, in cases of asthmatic bronchitis with definite benefit in 15 out of 17 cases.

I wish to report here two cases of asthmatic bronchitis in which the administration of lipiodol by the passive method has proved of distinct benefit. The method, as described by Ochsner, consists of the production of sensory anesthesia of the anterior tonsillar pillars so that the swallowing reflex is abolished and, after the introduction of a 10 per cent procaine solution as an anesthetic to the tracheobronchial mucosa, the iodized oil is taken on the back of the tongue and enters the pharynx. With the patient in the upright position, it then goes through the superior laryngeal orifice into the trachea. This procedure is probably best carried out by a laryngologist as it was in these cases. The technic, however, is not difficult.

Case 1.—K. W., an unmarried female, age 33, was first seen on October 31, 1927. She had had attacks of bronchitis since childhood and in the past ten years had had numerous asthmatic attacks. In the intervals between attacks she raised moderate amounts of thick sputum. The tonsils had been removed. Physical examination showed a marked emphysema and findings typical of asthmatic bronchitis. Blood pressure was 122/80. X-ray films of the chest were negative. Skin tests showed her to be slightly sensitive to horse dander, rabbit hair, and dog hair. Urinalysis was negative. Sputum specimens showed mixed infection. Diagnostic puncture of the maxillary sinuses showed no evidence of infection. Dental X-ray films showed one devitalized tooth.

---

*Read at the meeting of the Minnesota Society of Internal Medicine, November 9, 1931, St. Paul.

Treatment consisted of the following measures: (1) removal of the devitalized tooth, and (2) administration of an autogenous vaccine prepared from organisms found in the sputum. There was no improvement following this and she suffered from much fatigue and wheezing between the attacks of asthma.

On October 3, 1929, lipiodol was injected into the right bronchial tree. Fluoroscopic examination immediately afterward showed a slight cylindrical dilatation of the bronchi. The injection was repeated on the opposite side a few days later with some difficulty because of coughing and bronchospasm, but this was overcome by the administration of adrenalin hypodermatically. Lipiodol injections were repeated in April and June, 1930.

Since the iodized oil was first injected, the patient has reported only one mild attack of asthma and a few mild attacks of upper respiratory infection. Her sputum has greatly diminished in amount. She has resumed her occupation at full time. Although she still has some dyspnea on moderate exertion, she feels greatly improved.

Case 2.—A male, aged thirty-seven, was first seen February 20, 1928. At various times he had had dermatitis from exposure to primrose. His first attack of asthma occurred in June, 1927, following a respiratory infection. Attacks recurred at intervals of a few months and he had some cough, sputum and shortness of breath between attacks. Physical examination showed a well-developed man with emphysematous chest and coarse râles scattered throughout the lower chest. The tonsils were enlarged and cryptic. Heart tones were normal. The blood pressure was 130/70. Skin tests showed slight positive reaction to cheese, salmon, and horse dander. The sputum showed mixed infection. The blood count was normal throughout except that the differential count showed 7 per cent eosinophiles. The urine was normal. X-ray films of the chest were negative. Irrigation of the maxillary sinuses showed definite evidence of infection and the sinuses were irrigated repeatedly for this. The tonsils were removed.

As the patient showed only temporary improvement following these procedures, it was decided to instil lipiodol into the bronchi and this was done in January, 1930. The injection was repeated in August, 1930, November, 1930, and in March, 1931. X-ray films taken of the chest after the lipiodol instillation showed slight cylindrical dilatation of the bronchi but no evidence of bronchiectasis.

Following the injection he reported much improvement, with great diminution in the number of attacks of upper respiratory infection and asthma. While he is not entirely relieved of his bronchitis, he is nevertheless greatly improved.

These two cases are reported because it is felt that the instillation of iodized oil into the tracheobronchial tree was of marked benefit in them.

It is recognized that in asthma there are many instances of improvement or cure without any appreciable treatment, but I believe that in these cases the lipiodol had a definite effect on the bronchial infection and consequently on the number of asthmatic attacks.

INULIN

Inulin is a polysaccharide carbohydrate that resembles starch. It occurs in plants as a reserve carbohydrate in a few species that are edible. Foremost is the so-called Jerusalem artichoke, Helianthus tuberosus. Years ago attempts were made to feed Jerusalem artichokes to patients with diabetes because it had been found that the sugar output was not increased thereby. The assumption from such observations, however, that inulin can be utilized satisfactorily by the diabetic patient is by no means justified from such data. Obviously, any carbohydrate that cannot be readily digested would fail to be absorbed and accordingly fail to increase the sugar output. Despite the scientific evidence tending to diminish the probability of successful application of inulin-bearing plants to human nutrition, a number of capable investigators have concluded that Jerusalem artichokes actually improve the tolerance of patients as well as supply some energy that is directly utilized in the diabetic metabolism. Recent investigators believe that the reputed therapeutic value of Jerusalem artichokes in the diet of the diabetic patient, reported frequently by physicians from their personal experience, is based too often on uncontrolled observations and is a result both of over-enthusiasm on the part of the observer and of the tendency of human nature to anticipate results, even at the expense of erroneous conclusions. (Jour. A. M. A., February 6, 1932, p. 483.)

TREATMENT OF CHRONIC MORPHINE INTOXICATION

Walter P. Gardner, M.D.

Saint Paul

THE treatment of chronic morphine intoxication is an important matter, for this disease is one of the major medico-social problems of today. The so-called "morphine addict," or as he should more fittingly be termed, "the individual suffering from chronic morphine intoxication," is met with by every practitioner of medicine; how often one does not know, for it is not necessary that the patient exhibit pin point pupils, tremor of the hands, sallow complexion and moral degradation, and in fact often the closest scrutiny fails to bring to light any one of these symptoms. However, the number of those who apply for treatment of this disease, coupled with those in whom the illness is recognized during examination for other complaints, is considerable.

In the treatment of chronic morphine intoxication, I feel there are four important considerations: (1) The proper attitude of the physician and the patient toward one another; (2) discontinuance of the drug; (3) convalescence in the hospital; and (4) care after discharge from the hospital.

The feeling of the physician in regard to the condition is all important, for out of this grows his reaction to the patient, and from it, to a large extent, evolves the patient's attitude toward both the doctor and his illness.

During recent years a great change in feeling on the part of the physician in regard to "morphinism" has occurred. Where formerly it was generally regarded as a "vice" or "habit," it is now increasingly being recognized as a functional disease. If even a large minority of so-called "addicts" discontinued the use of the drug unaided, through their own efforts, one might rightly hold the majority responsible for not doing likewise, but less than one-fifth of one per cent accomplish this task. The logical explanation of this fact lies in the peculiar properties of the drug which affects the body and mind of the user in such a manner that attempts at discontinuance lead to extreme physical and mental suffering. The depression and mental anguish are intense and horrible in themselves, but moreover, they leave the user in no condition to bear physical pain. This functional disease involves the nervous system primarily, but the glandular system and metabolism are affected as well.

With this knowledge in hand the physician can now approach the problem from a sound point of view. He no longer considers the individual constitutionally inferior, a degenerate, or a potential criminal, but rather the victim of a disease. That this is the proper attitude is borne out by the facts that users are of all ages and of both sexes, and that this condition is not restricted to any social, economic, or intellectual group.

The attitude of the patient toward the doctor must be one of absolute confidence. Nothing engenders this more than a kindly, sympathetic, understanding, yet firm, manner on the part of the medical advisor. The patient must look at his condition as a disease that can be and must be overcome by a thorough coöperation with the physician and a resolute determination upon his (the patient's) part to get well.

With the above in mind, we will pass to a consideration of discontinuance of the drug. There are two general ways of accomplishing this, either by the substitution method or the systematic withdrawal method. The former, consisting of the substitution of cocaine, codein, heroin, opium, or the like for the morphine, has on the whole been abandoned, since the substitution remedies often lead to a new habit which is frequently added to the old. The latter, consisting of systematic withdrawal of the drug under the strictest supervision, is now practiced almost exclusively.

There are three chief ways by which systematic withdrawal may be accomplished. The oldest of these is the gradual withdrawal method, and a few still defend this process in a modified form. It consists of a very gradual reduction in the daily dose of morphine with palliative treatment of the accompanying symptoms. Its advantages are none, while its disadvantages are the exceedingly difficult task of controlling the patient so that he can not secure the drug secretly, prolongation of the abstinence symptoms, and prolonging the total period of treatment.

In 1875, some years after the introduction of this first method, the abrupt withdrawal method was described by Levenstein. This process consists of first placing the patient in strict confinement in an especially equipped hospital with reliable private day and night nurses in constant attendance, and then withdrawing the morphine in its entirety at a single stroke. This procedure has two points in its favor—certainty of success (as to discontinuance of the drug), and rapidity of accomplishment, but the fact that it can be practiced only in special hospitals and, more important still, the ever present danger to life by cardiac collapse offset these advantages.

The rapid withdrawal method introduced by Erlenmeyer in 1883 has had many modifications, and in its various forms is the most common system in use today. The literature contains an unusual number of modifications of Erlenmeyer's treatment, but all embody the same principles, namely, removal of the drug over a period of several days and treatment of the accompanying abstinence symptoms followed by a period of recuperation in the hospital. No attempt will be made to discuss these various modifications in this paper.

The following is an outline of the plan used by us (Riggs, Hengstler, and Gardner) for securing discontinuance of the drug. One cannot prescribe a cut and dried rigid routine schedule for the withdrawal of the morphine, but a general plan may be presented which has proved very satisfactory in our experience.

The patient, having evidenced a firm desire to get well, and an understanding of the attitude of physician or physicians in charge of the case toward himself and his disease, is placed in a hospital. He is isolated from friends and family with absolute restriction of visitors of any kind, and is not allowed to send or receive telephone messages, notes, or mail. His clothes, including his night clothing and bathrobe, are surrendered by him and thoroughly searched, as in his person. Withdrawal proper is then begun, either after a preliminary observation period of twenty-four to forty-eight hours or if there are no contraindications on physical examination, at once. If the physical condition is such that withdrawal seems risky, time for general physical upbuilding must be allowed.

The time for beginning of reduction having been determined, the patient is placed upon a dosage of about one-half the amount of morphine by hypodermic that he states he has been taking, or that observation has shown necessary to maintain his sense of well being. It seems best that this be given in divided doses at a definitely scheduled time, for instance at 6:00 and 10:00 a. m., and at 2:00, 6:00 and 10:00 p. m. The amount of morphine given at each of these hours is not the same, although the amount of solution in the hypodermic is kept constant. The late evening injection is the strongest, to help in securing a good night's rest; the early morning dose next in potency, the early afternoon hypodermic of about the same strength as the first morning dose, and the remaining two injections containing a still smaller amount of the drug. For example, if the average daily dose has been six grains per day, the total given on the first day of withdrawal would be three grains divided as follows: at 6:00 a. m. ¾ grain; at 10:00 a. m. ¼ grain; at 2:00 p. m. ½ grain; at 6:00 p. m. ¼ grain; and at 10:00 p. m. 1¼ grains. On the second day this amount would again be reduced by one half, *i.e.*, to 1½ grains. Each of the five injections is not reduced in strength by the same amount, but rather the relative size of the dose is kept the same, *i.e.*, the late evening dose is the strongest and the early morning injection next in strength as on the previous day. Each day the amount of morphine is reduced by one half of the previous day's total until within a period of several days all the morphine has been discontinued.

As the morphine is reduced, abstinence or withdrawal symptoms begin to appear. It often will not be necessary at first to confine the patient to his bed, but as discontinuance proceeds, it will be necessary to do so and he may even require restraints before the task is completed. Abstinence symptoms occurring with this process vary in degree with the individual case. They are briefly: restlessness, irritability, pain, nausea, and occasional vomiting, and in some instances signs of circulatory embarrassment, but almost never signs of threatened collapse. As the restlessness, irritability and pain appear and increase in intensity, sedatives are administered in the form of bromide, sulphonal, trional and luminal, including sodium luminal by hypodermic. Analgesics other than opium and its derivatives, and occasionally combined analgesic sedative preparations such as allonal or cibalgine are also used. Free catharsis, but not drastic purgation, is secured. Ice and ice cold drinks help relieve the nausea and vomiting. In case of cardiac embarrassment the usual supportive treatment is used and if collapse be feared morphine is given by hypodermic at once. By the use of these therapeutic agents, the patient is kept quiet and relatively comfortable.

As reduction proceeds, the 10:00 a. m. and 2:00 p. m. morphine injections may soon be replaced by sterile normal saline, or opportunity is here presented to give part of the necessary sedation by hypodermic in the form of sodium luminal. After several days none of the injections will contain morphine, the last to be substituted by placebo, or sodium luminal being the bedtime injection. At the time of withdrawal of the last morphine, a large amount of sedatives will be found necessary. It is to be noted that many times the final withdrawal precipitates a psychosis of the Korsakow's type, in which the patient, although confined to his bed, makes journeys from the hospital, oftentimes long complicated trips, especially at night, is disoriented and is often quite noisy. At this time it may be necessary to place the patient in the mental department of the hospital or to secure a private nurse for a short time. This mental condition always clears up entirely and usually is of only a few days to a week in duration, although it occasionally persists for a longer time. Some writers have attributed this psychosis to the sedatives used rather than to the withdrawal of the drug, but, in our opinion, it is due to the latter.

This is the general plan but it is not to be thought that this must be adhered to rigidly. At times, on any given day, it may be possible to substitute a placebo for a regular morphine hypodermic, or again it may be necessary to increase the strength of a previously scheduled injection; or in event of threatened collapse which almost never occurs with this method an additional injection of the drug may have to be given. The schedule may usually be picked up again in the last mentioned case, but occasionally the total amount may have to be increased and reduction continued again on a new schedule. It is best to make the schedule day by day in accordance with the condition of the patient. The advantages of the method outlined are: certainty of success as to discontinuance of the drug, as isolation of the patient precludes access to morphine; freedom from danger, as it is extremely seldom that collapse threatens the patient's life; and shorter duration of the abstinence symptoms, leaving a longer period for convalescence.

The withdrawal or discontinuance of the drug having been accomplished, the less difficult part of the treatment has been finished, for the convalescent period in the hospital and the care after discharge are most difficult to carry to a successful outcome. As to the convalescence in the hospital the following may be said. Mere withdrawal of the drug means nothing. It is necessary that a proper physical and mental condition be reached by the patient during his stay in the hospital if lasting results are to be obtained. How long a period this will require one cannot state beforehand, but as an average time one might suggest twelve to sixteen weeks. While it is true that at the end of six or eight weeks, the physical condition is satisfactory, the body weight is at a peak and normal sleep as a rule has returned, psychically the patient is not able to withstand all the influences of life outside the hospital without recourse to morphine. For example, he is not, at this time, ready to do regular mental work requiring concentration, for he lacks both power to concentrate and endurance. Gradually, ability to apply himself and to do mental work returns.
